Amniocentesis is a procedure done under ultrasound guidance where a long thin needle is inserted into the mother’s abdomen, then into the uterus, to withdraw a couple tablespoons of amniotic fluid (fluid surrounding the developing baby) to study. Measurement of the AFP in the amniotic fluid can then be done to test for problems such as omphalocele. In addition, a chromosome analysis for the baby can be performed on the cells contained in the amniotic fluid. When the AFP in the amniotic fluid is elevated, an additional test is used to look for the presence or absence of an enzyme found in nerve tissue, called acetylcholinesterase, or ACHE. ACHE is present in the amniotic fluid only when a baby has an opening such as spina bifida or an omphalocele. Not all babies with an omphalocele will cause the maternal serum screening test to be abnormal or to cause extra fluid accumulation, but many will. At birth, an omphalocele is diagnosed by visual/physical examination.

Treatment and management

Treatment and management of an omphalocele depends upon the size of the abnormality, whether the sac is intact or ruptured, and whether other health problems are present. A small omphalocele is usually

repaired by surgery shortly after birth, where an operation is performed to return the organs to the abdomen and close the opening in the abdominal wall. If the omphalocele is large, where most of the intestines, liver, and/or spleen are present outside of the body, the repair is done in stages because the abdomen is small and may not be able to hold all of the organs at once. Initially, sterile protective gauze is placed over the abdominal organs whether the omphalocele is large or small. The exposed organs are then gradually moved back into the abdomen over several days or weeks. The abdominal wall is surgically closed once all of the organs have been returned to the abdomen. Infants are often on a breathing machine (ventilator) until the abdominal cavity increases in size since returning the organs to the abdomen may crowd the lungs in the chest area.

Prognosis

The prognosis of an infant born with an omphalocele depends upon the size of the defect, whether there was a loss of blood flow to part of the intestines or other organs, and the extent of other abnormalities. The survival rate overall for an infant born with an isolated omphalocele has improved greatly over the past 40 years, from 60% to over 90%.

Oncogene

Definition

In a cell with normal control regulation (non-cancerous), genes produce proteins that provide regulated cell division. Cancer is the disease caused by cells that have lost their ability to control their regulation. The abnormal proteins allowing the non-regulated cancerous state are produced by genes known as oncogenes. The normal gene from which the oncogene evolved is called a proto-oncogene.

Description

History

The word "oncogene" comes from the Greek term "oncos," which means "tumor." Oncogenes were originally discovered in certain types of animal viruses that were capable of inducing tumors in the animals they infected. These viral oncogenes, called v-onc, were later found in human tumors, although most human cancers do not appear to be caused by viruses. Since their original discovery, hundreds of oncogenes have been found but only a small number of them are known to affect humans. Although different oncogenes have different functions, they are all somehow involved in the process of transformation (change) of normal cells to cancerous cells.

The transformation of normal cells into cancerous cells

The process by which normal cells are transformed into cancerous cells is a complex, multi-step process involving a breakdown in the normal cell cycle. Normally, a somatic cell goes through a growth cycle in which it

Molecular model of an oncogene protein. (Laguna Design/ Science Photo Library/Alamy)

produces new cells. The two main stages of this cycle are interphase (genetic material in the cell duplicates) and mitosis (the cell divides to produce two other identical cells). The process of cell division is necessary for the growth of tissues and organs of the body and for the replacement of damaged cells. Normal cells have a limited lifespan and only go through the cell cycle a limited number of times.

Different cell types are produced by the regulation of which genes in a given cell are allowed to be expressed. One way cancer is caused is by de-regulation of those genes related to control of the cell cycle and the development of oncogenes. If the oncogene is present in a skin cell, the patient will have skin cancer; in a breast cell, breast cancer will result, and so on.

Cells that lose control of their cell cycle and replicate out of control are called cancer cells. Cancer cells undergo many cell divisions often at a quicker rate than normal cells and do not have a limited lifespan. This allows them to eventually overwhelm the body with a large number of abnormal cells and eventually affect the functioning of the normal cells.

A cell becomes cancerous only after changes occur in a number of genes that are involved in the regulation of its cell cycle. A change in a regulatory gene can cause it to stop producing a normal regulatory protein or can produce an abnormal protein that does not regulate the cell in a normal manner. When changes occur in one regulatory gene this often causes changes in other regulatory genes. Cancers in different types of cells can be caused by changes in different types of regulatory genes.

Proto-oncogenes and tumor-suppressor genes are the two most common genes involved in regulating the cell cycle. Proto-oncogenes and tumor-suppressor genes have different functions in the cell cycle. Tumor-suppressor genes produce proteins that are involved in prevention of uncontrolled cell growth and division. Since two of each type of gene are inherited, two of each type of tumor-suppressor gene are also inherited. Both tumor suppressor genes of a pair need to be changed in order for the protein produced to stop functioning as a tumor suppressor. Mutated tumor-suppressor genes therefore act in an autosomal recessive manner.

Proto-oncogenes produce proteins that are largely involved in stimulating the growth and division of cells in a controlled manner. Each proto-oncogene produces a different protein that has a unique role in regulating the cell cycles of particular types of cells. We inherit two of each type of proto-oncogene. A change in only one proto-oncogene of a pair converts it into an oncogene. The oncogene produces an abnormal protein, which is somehow involved in stimulating uncontrolled cell

growth. An oncogene acts in an autosomal dominant manner since only one proto-oncogene of a pair needs to be changed in the formation of an oncogene.

Classes of proto-oncogene

There are five major classes of proto-oncogene/ oncogenes: (1) growth factors, (2) growth factor receptors, (3) signal transducers (4) transcription factors, and (5) programmed cell death regulators.

GROWTH FACTORS. Some proto-oncogenes produce proteins, called growth factors, which indirectly stimulate growth of the cell by activating receptors on the surface of the cell. Different growth factors activate different receptors, found on different cells of the body. Mutations in growth factor proto-oncogene result in oncogenes that promote uncontrolled growth in cells for which they have a receptor. For example, platelet-derived growth factor (PDGF) is a proto-oncogene that helps to promote wound healing by stimulating the growth of cells around a wound. PDGF can be mutated into an oncogene called v-sis (PDGFB), which is often present in connective-tissue tumors.

GROWTH FACTOR RECEPTORS. Growth factor receptors are found on the surface of cells and are activated by growth factors. Growth factors send signals to the center of the cell (nucleus) and stimulate cells that are at rest to enter the cell cycle. Different cells have different growth factors receptors. Mutations in a proto-oncogene that are growth factor receptors can result in oncogenes that produce receptors that do not require growth factors to stimulate cell growth. Overstimulation of cells to enter the cell cycle can result and promote uncontrolled cell growth. Most proto-oncogene growth factor receptors are called tyrosine kinases and are very involved in controlling cell shape and growth. One example of a tyrosine kinase is called GDFNR. The RET (rearranged during transfection) oncogene is a mutated form of GDFNR and is commonly found in cancerous thyroid cells.

SIGNAL TRANSDUCERS. Signal transducers are proteins that relay cell cycle stimulation signals, from growth factor receptors to proteins in the nucleus of the cell. The transfer of signals to the nucleus is a stepwise process that involves a large number of proto-oncogenes and is often called the signal transduction cascade. Mutations in proto-oncogene involved in this cascade can cause unregulated activity, which can result in abnormal cell proliferation. Signal transducer oncogenes are the largest class of oncogenes. The RAS family is a group of 50 related signal transducer oncogenes that are found in approximately 20% of tumors.

TRANSCRIPTION FACTORS. Transcription factors are proteins found in the nucleus of the cell that ultimately

KEY TERMS

Autosomal dominant manner—An abnormal gene on one of the 22 pairs of non-sex chromosomes that will display the defect when only one copy is inherited.

Benign—A non-cancerous tumor that does not spread and is not life-threatening.

Cell—The smallest living units of the body, which group together to form tissues and help the body perform specific functions.

Chromosome—A microscopic thread-like structure found within each cell of the body that consists of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Gene—A building block of inheritance, which contains the instructions for the production of a particular protein, and is made up of a molecular sequence found on a section of DNA. Each gene is found on a precise location on a chromosome.

Leukemia—Cancer of the blood forming organs that results in an overproduction of white blood cells.

Lymphoma—A malignant tumor of the lymph nodes.

Mitosis—The process by which a somatic cell divides.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and can be transmitted to offspring.

Nucleus—The central part of a cell that contains most of its genetic material, including chromosomes and DNA.

Parathyroid glands—A pair of glands adjacent to the thyroid gland that primarily regulate blood calcium levels.

Pheochromocytoma—A small vascular tumor of the inner region of the adrenal gland. The tumor causes uncontrolled and irregular secretion of certain hormones.

Proliferation—The growth or production of cells.

Protein—Important building blocks of the body, composed of amino acids, involved in the formation of body structures and controlling the basic functions of the human body.

Proto-oncogene—A gene involved in stimulating the normal growth and division of cells in a controlled manner.

Replicate—Produce identical copies of itself.

Somatic cells—All the cells of the body except for the egg and sperm cells.

Translocation—The transfer of one part of a chromosome to another chromosome during cell division. A balanced translocation occurs when pieces from two different chromosomes exchange places without loss or gain of any chromosome material. An unbalanced translocation involves the unequal loss or gain of genetic information between two chromosomes.

Tumor suppressor gene—Genes involved in controlling normal cell growth and preventing cancer.

receive the signals from the growth factor receptors. Transcription factors directly control the expression of genes that are involved in the growth and proliferation of cells. Transcription factors produced by oncogenes typically do not require growth factor receptor stimulation and thus can result in uncontrolled cell proliferation. Transcription factor proto-oncogenes are often changed into oncogenes by chromosomal translocations in leukemias, lymphomas, and solid tumors. C-myc is a common transcription factor oncogene that results from a chromosomal translocation and is often found in leukemias and lymphomas.

PROGRAMMED CELL DEATH REGULATORS. Normal cells have a predetermined lifespan and different genes regulate their growth and death. Cells that have been damaged or have an abnormal cell cycle may develop into cancer cells. Usually these cells are destroyed

through a process called programmed cell death (apoptosis). Cells that have developed into cancer cells, however, do not undergo apoptosis. Mutated proto-oncogenes may inhibit the death of abnormal cells, which can lead to the formation and spread of cancer. The bcl-2 oncogene, for example, inhibits cell death in cancerous cells of the immune system.

Mechanisms of transformation of proto-oncogene into oncogenes

It is not known in most cases what triggers a particular proto-oncogene to change into an oncogene. There appear to be environmental triggers such as exposure to toxic chemicals. There also appear to be genetic triggers since changes in other genes in a particular cell can trigger changes in proto-oncogenes.

The mechanisms through which proto-oncogenes are changed into oncogenes are, however, better understood. Proto-oncogenes are transformed into oncogenes through: (1) mutation, (2) chromosomal translocation, and (3) gene amplification.

A tiny change, called a mutation, in a proto-oncogene can convert it into an oncogene. The mutation results in an oncogene that produces a protein with an abnormal structure. These mutations often make the protein resistant to regulation and cause uncontrolled and continuous activity of the protein. The RAS family of oncogenes, found in approximately 20% of tumors, are examples of oncogenes caused by mutations.

Chromosomal translocations, which result from errors in mitosis, have also been implicated in the transformation of proto-oncogenes into oncogenes. Chromosomal translocations result in the transfer of a proto-oncogene from its normal location on a chromosome to a different location on another chromosome. Sometimes this translocation results in the transfer of a proto-oncogene next to a gene involved in the immune system. This results in an oncogene that is controlled by the immune system gene and as a result becomes deregulated. One example of this mechanism is the transfer of the c-myc proto-oncogene from its normal location on chromosome 8 to a location near an immune system gene on chromosome 14. This translocation results in the deregulation of c-myc and is involved in the development of Burkitt's lymphoma. The translocated c-myc proto-oncogene is found in the cancer cells of approximately 85% of people with Burkitt's lymphoma.

In other cases, the translocation results in the fusion of a proto-oncogene with another gene. The resulting oncogene produces an unregulated protein that is involved in stimulating uncontrolled cell proliferation. The first discovered fusion oncogene resulted from a Philadelphia chromosome translocation. This type of translocation is found in the leukemia cells of greater than 95% of patients with a chronic form of leukemia. The Philadelphia chromosome translocation results in the fusion of the c-abl proto-oncogene, normally found on chromosome 9, to the *BCR* gene found on chromosome 22. The fused gene produces an unregulated transcription factor protein that has a different structure than the normal protein. It is not known how this protein contributes to the formation of cancer cells.

Some oncogenes result when multiple copies of a proto-oncogene are created (gene amplification). Gene amplification often results in hundreds of copies of a gene, which results in increased production of proteins and increased cell growth. Multiple copies of proto-oncogenes are found in many tumors. Sometimes

amplified genes form separate chromosomes called double minute chromosomes and sometimes they are found within normal chromosomes.

Inherited oncogenes

In most cases, oncogenes result from changes in proto-oncogenes in select somatic cells and are not passed on to future generations. People with an inherited oncogene, however, do exist. They possess one changed proto-oncogene (oncogene) and one unchanged proto-oncogene in all of their somatic cells. The somatic cells have two of each chromosome and therefore two of each gene since one of each type of chromosome is inherited from the mother in the egg cell and one of each is inherited from the father in the sperm cell. The egg and sperm cells have undergone a number of divisions in their cell cycle and therefore only contain one of each type of chromosome and one of each type of gene. A person with an inherited oncogene has a changed proto-oncogene in approximately 50% of their egg or sperm cells and an unchanged proto-oncogene in the other 50% of their egg or sperm cells, and therefore has a 50% chance of passing this oncogene on to their children.

A person only has to inherit a change in one proto-oncogene of a pair to have an increased risk of cancer. This is called autosomal dominant inheritance. Not all people with an inherited oncogene develop cancer, since mutations in other genes that regulate the cell cycle need to occur in a cell for it to be transformed into a cancerous cell. The presence of an oncogene in a cell does, however, make it more likely that changes will occur in other regulatory genes. The degree of cancer risk depends on the type of oncogene inherited as well as other genetic factors and environmental exposures. The types of cancers that are likely to develop depend on the type of oncogene that has been inherited.

Multiple endocrine neoplasia type II (MENII) is one example of a condition caused by an inherited oncogene. People with MENII have usually inherited the *RET* oncogene. They have approximately a 70% chance of developing thyroid cancer, a 50% chance of developing a tumor of the adrenal glands (pheochromocytoma), and about a 5%–10% chance of developing symptomatic parathyroid disease.

Oncogenes as targets for cancer treatment

The discovery of oncogenes approximately 20 years ago has played an important role in developing an understanding of cancer. Oncogenes promise to play an even greater role in development of improved cancer therapies since oncogenes may be important targets for drugs that are used for the treatment of cancer. The goal of

these therapies is to selectively destroy cancer cells while leaving normal cells intact. Many anti-cancer therapies currently under development are designed to interfere with oncogenic signal transducer proteins, which relay the signals involved in triggering the abnormal growth of tumor cells. Other therapies hope to trigger specific oncogenes to cause programmed cell death in cancer cells. Whatever the mechanism by which they operate, it is hoped that these experimental therapies will offer a great improvement over current cancer treatments.

Opitz syndrome

Definition

Opitz syndrome is a heterogeneous genetic condition characterized by a range of midline birth defects such as hypertelorism, clefts in the lips and larynx, heart defects, hypospadias, and agenesis of the corpus callosum.

Description

Opitz syndrome or Opitz G/BBB syndrome, as it is sometimes called, includes G syndrome and BBB syndrome, which were originally thought to be two different syndromes, as described in 1969 by Dr. John Opitz. G

Frequencies of common conditions associated with Opitz syndrome

Hypospadias	93%	LTE cleft/fistula	38%
Hypertelorism	91%	Cleft lip and palate	32%
Swallowing problems	81%	Strabismus	28%
Ear abnormalities	72%	Heart defects	27%
Developmental delay	43%	Imperforate anus	21%
Kidney anomalies	42%	Undescended testes	20%

(Gale)

syndrome was named after one family affected with the syndrome whose last name began with the initial G, and BBB syndrome was named after the surname of three different families. Subsequent research suggested that these two conditions were one disorder, but researchers could not agree on how the disorder was inherited. It wasn't until 1995 that Dr. Nathaniel Robin and his colleagues demonstrated that Opitz syndrome had both X-linked and autosomal dominant forms.

Opitz syndrome is a complex condition that has many symptoms, most of which affect organs along the midline of the body such as clefts in the lip and larynx, heart defects, hypospadias, and agenesis of the corpus callosum. Opitz syndrome has variable expressivity, which means that different people with the disorder can have different symptoms. This condition also has decreased penetrance, which means that not all people who inherit the disorder will have symptoms.

Genetic profile

Opitz syndrome is a genetically heterogeneous condition. There appear to be at least two to three genes that can cause Opitz syndrome when changed (mutated) or deleted. Opitz syndrome can be caused by changes in genes found on the X chromosome (X-linked) and changes in or deletion of a gene found on chromosome 22 (autosomal dominant).

Chromosomes, genes, and proteins

Each cell of the body, except for the egg and sperm cells, contains 23 pairs of chromosomes—46 chromosomes in total. The egg and sperm cells contain only one of each type of chromosome and therefore contain 23 chromosomes in total. Males and females have 22 pairs of chromosomes, called the autosomes, numbered 1 to 22 in order of decreasing size. The other pair of chromosomes, called the sex chromosomes, determines the sex of the individual. Women possess two identical chromosomes called the X chromosomes, while men possess one X chromosome and one Y chromosome. Since every egg cell contains an X chromosome, women pass on the X

chromosome to their daughters and sons. Some sperm cells contain an X chromosome, and some sperm cells contain a Y chromosome. Men pass the X chromosome on to their daughters and the Y chromosome on to their sons. Each type of chromosome contains different genes that are found at specific locations along the chromosome. Men and women inherit two of each type of autosomal gene since they inherit two of each type of autosome. Women inherit two of each type of X-linked gene since they possess two X chromosomes. Men inherit only one of each X-linked gene since they possess only one X chromosome.

Each gene contains the instructions for the production of a particular protein. The proteins produced by genes have many functions and work together to create the traits of the human body such as hair and eye color and are involved in controlling the basic functions of the human body. Changes or deletions of genes can cause them to produce abnormal protein, less protein, or no protein. This can prevent the protein from functioning normally.

Autosomal dominant Opitz syndrome

The gene responsible for the autosomal dominant form of Opitz syndrome is known as the *SPECCIL* gene, which is located on chromosome 22q11. In some cases, the deletion or gene change is inherited from either the mother or father who has the gene change or deletion in one chromosome 22 in the somatic cells. The other chromosome 22 found in each of the somatic cells is normal. Some of the egg or sperm cells contain the gene change or deletion in chromosome 22, and some contain a normal chromosome 22. In other cases the deletion has occurred spontaneously during conception or is only found in some of the egg or sperm cells of either parent but not in the other cells of the body.

Parents who have had a child with an autosomal dominant form of Opitz syndrome may or may not be at increased risk for having other affected children. If one of the parents is diagnosed with Opitz syndrome, then each of the children has a 50% chance of inheriting the condition. If neither parent has symptoms of Opitz syndrome or possesses a deletion, then it becomes more difficult to assess their chances of having other affected children.

In many cases they would not be at increased risk since the gene alteration occurred spontaneously in the embryo during conception. It is possible, however, that one of the parents is a carrier, meaning he or she possesses a change in the autosomal dominant Opitz gene but does not have any obvious symptoms. This parent's

children would each have a 50% chance of inheriting the Opitz gene.

X-linked Opitz syndrome

Some people with the X-linked form of Opitz syndrome have a change (mutation) in a gene found on the X chromosome called the *MID1* (midline1) gene. It is believed that the *MID* genes produce proteins involved in the development of midline organs. Changes in the *MID* gene prevent the production of enough normal protein for normal organ development.

The X-linked form of Opitz syndrome is inherited differently by men and women. A woman with an X-linked form of Opitz syndrome has typically inherited a changed *MID* gene from her mother and a changed *MID* gene from her father. This occurs very infrequently. All of this woman's sons will have Opitz syndrome, and all of her daughters will be carriers for Opitz syndrome. Only women can be carriers for Opitz syndrome, since carriers possess one changed *MID* gene and one unchanged *MID* gene. Most carriers for the X-linked form of Opitz syndrome do not have symptoms, since one normal *MID* gene is usually sufficient to promote normal development. Some carriers do have symptoms, but they tend to be very mild. Daughters of carriers of Opitz syndrome have a 50% chance of being carriers, and sons have a 50% chance of being affected with Opitz syndrome. A man with an X-linked form of Opitz syndrome will have normal sons, but all of his daughters will be carriers.

Demographics

Opitz syndrome is a rare disorder that appears to affect all ethnic groups. The frequency of this disorder is unknown, since people with this disorder exhibit a wide range of symptoms, making it difficult to diagnose. Many people possess mild or non-detectable symptoms.

Signs and symptoms

People with Opitz syndrome exhibit a wide range of medical problems and in some cases may not exhibit any detectable symptoms. This may be due in part to the genetic heterogeneity of this condition. Even people with Opitz syndrome who are from the same family can have different problems. This may mean there are other genetic and non-genetic factors that influence the development of symptoms in individuals who have inherited a changed or deleted Opitz gene. Most individuals with Opitz syndrome only have a few symptoms of the disorder, such as wide-set eyes and a broad, prominent forehead. Opitz syndrome can, however, affect many of the organs and structures of the body and primarily

KEY TERMS

Agenesis of the corpus callosum—Failure of the corpus callosum to form and develop. The corpus callosum is the band of nerve fibers located between the two sides, or hemispheres, of the brain.

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman’s abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Anomaly—Different from the normal or expected. Unusual or irregular structure.

Autosome—Chromosomes that do not determine the sex of an individual.

Chromosome—A microscopic thread-like structure found within each cell of the body that consists of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Cleft—An elongated opening or slit in an organ.

Cleft palate—A congenital malformation in which there is an abnormal opening in the roof of the mouth that allows the nasal passages and the mouth to be improperly connected.

Congenital—Refers to a disorder that is present at birth.

Cryptorchidism—A condition in which one or both testes fail to descend normally.

Deletion—The absence of genetic material that is normally found in a chromosome. Often, the genetic material is missing due to an error in replication of an egg or sperm cell.

Deoxyribonucleic acid (DNA)—The genetic material in cells that holds the inherited instructions for growth, development, and cellular functioning.

DNA testing—Analysis of DNA (the genetic component of cells) in order to determine changes in genes that may indicate a specific disorder.

Esophagus—The part of the digestive tract that connects the mouth and stomach; the food pipe.

FISH (fluorescence in situ hybridization)—Technique used to detect small deletions or rearrangements

affects the development of midline organs. The most common symptoms are hypertelorism (wide-spaced eyes); broad, prominent forehead; heart defects; hypospadias (urinary opening of the penis present on the underside of the penis instead of its normal location at the tip); undescended testicles; an abnormality of the anal opening; agenesis of the corpus callosum (absence of the tissue that connects the two sides of the brain); cleft lip; and clefts and abnormalities of the pharynx (throat) and larynx (voice-box), trachea (wind-pipe), and esophagus.

People with Opitz syndrome usually have a distinctive look to the face, such as a broad, prominent forehead; cleft lip; wide-set eyes that may be crossed; wide noses with upturned nostrils; small chins or jaws; malformed ears; crowded, absent, or misplaced teeth; and hair that may form a “widow’s peak.” In many cases, the head may appear large or small and out of proportion to the rest of the body.

Often, people with Opitz syndrome have difficulties swallowing because of abnormalities in the pharynx, larynx, trachea, or esophagus. This can sometimes result in

food entering the trachea instead of the esophagus, which can cause damage to the lungs and pneumonia. It can also sometimes be fatal in small infants. Abnormalities in the trachea can sometimes make breathing difficult and may result in a hoarse or weak voice and wheezing.

Both males and females may have abnormal genitals and abnormalities in the anal opening. Males can have hypospadias and undescended testicles, and girls may have minor malformation of their external genitalia. Heart defects are also often present, and abnormalities of the kidney can be present as well. Intelligence is usually normal, but mild intellectual disability can sometimes be present. Twins appear more common in families affected with Opitz syndrome.

Males and females with the dominant form of Opitz syndrome are equally likely to have symptoms, whereas carrier females with the X-linked form of Opitz syndrome are less likely to have symptoms than males with the condition. In general, males with the X-linked form of Opitz syndrome tend to be more severely affected than females and males with the autosomal dominant form of Opitz syndrome. People with X-linked Opitz syndrome and

in chromosomes by attempting to attach a fluorescent (glowing) piece of a chromosome to a sample of cells obtained from a patient.

Gene—A building block of inheritance, which contains the instructions for the production of a particular protein and is made up of a molecular sequence found on a section of DNA. Each gene is found on a precise location on a chromosome.

Geneticist—A specialist (MD or PhD) who has training and certification in diagnosing, managing, and counseling individuals/families with genetic disorders. Genetic counselors hold a master's degree in medical genetics and provide many of the same services as geneticists.

Heterogeneous—A set of symptoms or a disorder caused by several different gene mutations.

Hypertelorism—A wider-than-normal space between the eyes.

Hypospadias—An abnormality of the penis in which the urethral opening is located on the underside of the penis rather than at its tip.

Hypotonia—Reduced or diminished muscle tone.

Microcephaly—An abnormally small head.

Midline defects—Defects involving organs along the center of the body such as the lips, penis, and corpus callosum.

Midline organs—Organs found along the center of the body such as the lips, penis, and corpus callosum.

Polydactyly—The presence of extra fingers or toes.

Prenatal testing—Testing for a disease such as a genetic condition in an unborn baby.

Sex chromosomes—The X and Y chromosomes that determine the sex of the individual.

Somatic cells—All the cells of the body except for the egg and sperm cells.

Strabismus—An improper muscle balance of the ocular muscles resulting in crossed or divergent eyes.

Syndactyly—Webbing or fusion between the fingers or toes.

Ultrasound—An imaging technique that uses sound waves to help visualize internal structures in the body.

Undescended testicles—Testicles that failed to move from the abdomen to the scrotum during the development of the fetus.

X-linked gene—A gene found on the X chromosome.

dominant Opitz syndrome generally appear to exhibit the same range of symptoms. The only known exceptions are upturned nostrils and clefts at the back of throat, which appear to only occur in people with X-linked Opitz syndrome.

Diagnosis

Diagnostic evaluation

The diagnosis and cause of Opitz syndrome is often difficult to establish. In most cases, it is diagnosed through a clinical evaluation and not through a blood test. This means that a genetic specialist (geneticist) has examined the patient and found enough symptoms of Opitz syndrome to make a diagnosis. Since not all patients have obvious symptoms or even any symptoms at all, this can be a difficult task. It can also be difficult to establish whether an individual has an X-linked form or an autosomal dominant form, and whether it has been inherited or occurred spontaneously. In many cases, the geneticist has to rely on physical examinations or pictures of multiple family members and a description of the family's medical history to establish the cause of

Opitz syndrome. In some cases the cause cannot be established.

Sometimes a clinical diagnosis is confirmed through fluorescence in situ hybridization (FISH). FISH testing can detect whether a person has a deletion of the region of chromosome 22 that is associated with Opitz syndrome. Fluorescent (glowing) pieces of DNA containing the region that is deleted in Opitz syndrome are mixed with a sample of cells obtained from a blood sample. If there is a deletion in one of the chromosomes, the DNA will only stick to one chromosome and not the other and only one glowing section of a chromosome will be visible instead of two. Most patients with the autosomal dominant form of Opitz syndrome cannot be diagnosed through FISH testing since they possess a tiny change in the gene that cannot be detected with the procedure. As of early 2015, DNA testing for the X-linked form of Opitz disease was available through clinical laboratories.

Prenatal testing

It is difficult to diagnose Opitz syndrome in a baby prior to its birth. Sometimes doctors and technicians

QUESTIONS TO ASK YOUR DOCTOR

- What are the characteristic features of Opitz syndrome?
- On what tests or other measures is a differential diagnosis of Opitz syndrome based?
- What kinds of treatments are typically necessary for a child born with Opitz syndrome?
- Can you recommend an organization that provides information about this genetic condition and support for parents who have a child with Opitz syndrome?

(ultrasonographers) who specialize in performing ultrasound evaluations are able to see physical features of Opitz syndrome in the fetus. Some of the features they may look for in the ultrasound evaluation are heart defects, wide spacing between the eyes, clefts in the lip, hypospadias, and agenesis of the corpus callosum. It is very difficult, however, even for experts to diagnose or rule out Opitz syndrome through an ultrasound evaluation.

Opitz syndrome can be definitively diagnosed in a baby prior to its birth if an *MID* gene change is detected in the mother or if a deletion in chromosome 22 is detected in the mother or father. Cells from the baby are obtained through amniocentesis or chorionic villus sampling. These cells are analyzed for the particular *MID* gene change or chromosome 22 deletion found in one of the parents.

Treatment and management

There was no cure for Opitz syndrome and no treatment for the underlying condition. Management of the condition involves diagnosing and managing the symptoms. Clefts, heart defects, and genital abnormalities can often be repaired by surgery. Feeding difficulties can sometimes be managed using feeding tubes through the nose, stomach, or small intestine. Anti-reflux medications can be prescribed to lessen the risk for aspiration until laryngeal function is demonstrated. Early recognition and intervention with special education may help individuals with intellectual disability.

Prognosis

For most patients, the prognosis and quality of life of Opitz syndrome is good, with individuals typically living a normal lifespan. The prognosis, however, is very dependent on the type of organ abnormality and the

quality of medical care. Patients with severe heart defects and major abnormalities in the trachea and esophagus may have a poorer prognosis.

Oral-facial-digital syndrome

Definition

Oral-facial-digital (OFD) syndrome is a generic name for a variety of different genetic disorders that result in malformations of the mouth, teeth, jaw, facial bones, hands, and feet.

Description

Oral-facial-digital syndrome includes several different, but possibly related, genetic disorders. OFD syndromes are also referred to as digito-oro-facial syndromes. There are 13 different OFD syndromes,

identified as OFD syndrome type I, type II, and so on. OFD syndromes are so named because they all cause changes in the oral structures, including the tongue, teeth, and jaw; the facial structures, including the head, eyes, and nose; and the digits (fingers and toes). OFD syndromes are also frequently associated with developmental delay.

The different OFD syndromes are distinguished from each other based on the specific physical symptoms and the mode of inheritance. There are many alternate names for OFD syndromes. A partial list of these is:

- OFD syndrome type I: Gorlin syndrome I, Gorlin-Psaume syndrome, Papillon-Leage syndrome
- OFD syndrome type II: Mohr syndrome, Mohr-Claussen syndrome
- OFD syndrome type III: Sugarman syndrome
- OFD syndrome type IV: Baraitser-Burn syndrome
- OFD syndrome type V: Thurston syndrome

One of the traits found in individuals with OFD syndrome is webbing of the fingers and toes. (Chassenet/BSIP SA/Alamy)

KEY TERM

Digit—A finger or toe.

- OFD syndrome type VI: Varadi syndrome, Varadi-Papp syndrome
- OFD syndrome type VII: Whelan syndrome

Genetic profile

The mode of inheritance of OFD syndrome depends on the type of the syndrome. Type I is inherited as an X-linked dominant trait and is only found in females because it is fatal in males. X-linked means that the syndrome is carried on the female sex chromosome, while dominant means that only one parent has to pass on the gene mutation in order for the child to be affected with the syndrome.

OFD syndrome type VII is inherited either as an X-linked or autosomal dominant pattern of inheritance. Autosomal means that the syndrome is not carried on a sex chromosome.

OFD syndrome types II, III, IV, V, and VI are passed on through an autosomal recessive pattern of inheritance. Recessive means that both parents must carry the gene mutation in order for their child to have the disorder.

OFD syndrome types VIII and IX are characterized by either an autosomal or X-linked recessive pattern of inheritance.

The gene location for OFD syndrome type I has been assigned to Xp22.3-22.2, or on the 22nd band of the p arm of the X chromosome. The specific gene mutations responsible for the other types of OFD syndrome has not been identified.

Demographics

There does not appear to be any clear-cut ethnic pattern to the incidence of OFD syndrome. Most types of OFD syndrome affect males and females with equal probability, although type I, the most common type, affects only females (since it is lethal in males before birth). The estimated incidence of OFD syndrome is between 1 in 50,000 to 250,000 infants, with most of the cases being of the type I variety.

Signs and symptoms

The symptoms observed in people affected by OFD syndrome vary depending on the specific type of the syndrome. In general, the symptoms include the following:

QUESTIONS TO ASK YOUR DOCTOR

- How did this disorder get its name?
- What signs and symptoms are typically associated with oral-facial-digital syndrome?
- What information is available about the genetic basis of this condition?
- What information is needed in order to make a prognosis for any particular individual with this disorder?

Oral features:

- Cleft lip
- Cleft palate or highly arched palate
- Lobed or split tongue
- Tumors of the tongue
- Missing or extra teeth
- Gum disease
- Misaligned bite
- Smaller than normal jaw

Facial features:

- Small or wide set eyes
- Missing structures of the eye
- Broad base or tip of the nose
- One nostril smaller than the other
- Low-set or angled ears

Digital features:

- Extra fingers or toes
- Abnormally short fingers
- Webbing between fingers or toes
- Clubfoot
- Permanently flexed fingers

Mental development and central nervous system:

- Intellectual disabilities
- Brain abnormalities
- Seizures
- Spasmodic movements or tics
- Delayed motor and speech development

Other:

- Growth retardation
- Cardiovascular abnormalities

- Sunken chest
- Susceptibility to respiratory infection

Diagnosis

Diagnosis is usually made based on the observation of clinical symptoms. There is currently no medical test that can definitively confirm the diagnosis of OFD syndrome, with the exception of genetic screening for OFD syndrome type I.

Treatment and management

Treatment of OFD syndrome is directed toward the specific symptoms of each case. Surgical correction of the oral and facial malformations associated with OFD syndrome is often required.

Prognosis

Prognosis depends on the specific type of OFD syndrome and the symptoms present in the individual. OFD syndrome type I is lethal in males before birth. However, other types of OFD syndrome are found in both males and females. Due to the wide variety of symptoms seen in the 13 types of the syndrome, overall survival rates are not available.

Organic acidemias

Definition

Organic acidemias are a collection of amino and fatty acid oxidation disorders that cause non-amino organic acids to accumulate and be excreted in the urine.

Description

Organic acidemias are divided into two categories: disorders of amino acid metabolism and disorders involving fatty acid oxidation. There are several dozen different organic acidemia disorders. They are caused by inherited deficiencies in specific enzymes involved in the breakdown of branched-chain amino acids, lysine and tryptophan, or fatty acids. Some of these disorders have more than one cause.

Amino acids are chemical compounds from which proteins are made. There are about 40 amino acids in the human body. Proteins in the body are formed through various combinations of roughly half of these amino acids. The other 20 play different roles in metabolism. Organic acidemias involving amino acid metabolism disorders include isovaleric acidemia, 3-methylcrotonylglycemia, combined carboxylase deficiency, hydroxymethylglutaric acidemia, propionic acidemia, methylmalonic acidemia, beta-ketothiolase deficiency, and glutaric acidemia type I.

Fatty acids, part of a larger group of organic acids, are caused by the breakdown of fats and oils in the body. Organic acidemias caused by fatty acid oxidation disorders include glutaric acidemia type II short-chain acyl-CoA dehydrogenase (SCAD) deficiency, medium-chain acyl-CoA dehydrogenase (MCAD) deficiency, long-chain acyl-CoA dehydrogenase (LCAD) deficiency, very long-chain acyl-CoA dehydrogenase (VLCAD) deficiency, and long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency.

Most organic acidemias are considered rare, occurring in less than 1 in 5,000 persons. However, MCAD occurs in about 1 in 17,000 births. Most of these disorders produce life-threatening illnesses that can occur in

newborns, infants, children, and adults. In nearly all cases, though, the symptoms appear during the first few years of life, usually in children age two or younger. If left undiagnosed and untreated in young children, they can also delay physical development.

Genetic profile

Genes are the blueprint for the human body, directing the development of cells and tissue. Mutations in some genes can cause genetic disorders such as the organic acidemias. Every cell in the body has 23 pairs of chromosomes, 22 pairs of which contain two copies of individual genes. The 23rd pair of chromosomes is called the sex chromosome because it determines a person's gender. Men have an X and a Y chromosome while women have two X chromosomes.

Organic acidemias are generally believed to be autosomal recessive disorders that affect males and females. Autosomal means that the gene does not reside on the sex chromosome. People with only one abnormal gene are carriers but since the gene is recessive, they do not have the disorder. Their children will be carriers of the disorder 50% of the time but not show symptoms of the disease. Both parents must have one of the abnormal genes for a child to have symptoms of an organic acidemia. When both parents have the abnormal gene, there is a 25% chance each child will inherit both abnormal genes and have the disease. There is a 50% chance each child will inherit one abnormal gene and become a carrier of the disorder but not have the disease itself. There is a 25% chance each child will inherit neither abnormal gene and not have the disease nor be a carrier.

Demographics

Organic acidemias affect males and females roughly equally. The disorders primarily occur in Caucasian children of Northern European ancestry, such as English, Irish, German, French, and Swedish. In a 1994 study by Duke University Medical Center, 120 subjects with MCAD were studied. Of these, 118 were Caucasian, one was African American, and one was Native American; 65 were female and 55 were male; and 112 were from the United States while the other eight were from Great Britain, Canada, Australia, and Ireland.

Signs and symptoms

Symptoms of organic acidemias vary with type and sometimes even within a specific disorder. Isovaleric acidemia (IA) can present itself in two ways: acute severe or chronic intermittent. Roughly half of IA patients have the acute severe disorder and half the chronic intermittent

KEY TERMS

Acidosis—A condition of decreased alkalinity resulting from abnormally high acid levels (low pH) in the blood and tissues. Usually indicated by sickly sweet breath, headaches, nausea, vomiting, and visual impairments.

Alopecia—Loss of hair or baldness.

Biotin—A growth vitamin of the vitamin B complex found naturally in liver, egg yolks, and yeast.

Branched-chain—An open chain of atoms having one or more side chains.

Dystonia—Painful involuntary muscle cramps or spasms.

Homocysteine—An amino acid that is not used to produce proteins in the human body.

Hyperammonemia—An excess of ammonia in the blood.

Hypotonia—Reduced or diminished muscle tone.

Ketoacidosis—A condition that results when organic compounds (such as propionic acid, ketones, and fatty acids) build up in the blood and urine.

Ketolactic acidosis—The overproduction of ketones and lactic acid.

Ketonuria—The presence of excess ketone bodies (organic carbohydrate-related compounds) in the urine.

L-carnitine—A substance made in the body that carries wastes from the body's cells into the urine.

Lysine—A crystalline basic amino acid essential to nutrition.

Metabolic acidosis—High acidity (low pH) in the body due to abnormal metabolism, excessive acid intake, or retention in the kidneys.

Neutropenia—A condition in which the number of leukocytes (a type of white or colorless blood cell) is abnormally low, mainly in neutrophils (a type of blood cell).

Organic aciduria—The condition of having organic acid in the urine.

Pancytopenia—An abnormal reduction in the number of erythrocytes (red blood cells), leukocytes (a type of white or colorless blood cell), and blood platelets (a type of cell that aids in blood clotting) in the blood.

Thrombocytopenia—A persistent decrease in the number of blood platelets usually associated with hemorrhaging.

Tryptophan—A crystalline amino acid widely distributed in proteins and essential to human life.

type. In acute severe cases, patients are healthy at birth but show symptoms between 1 to 14 days later. These symptoms include vomiting, refusal to eat, dehydration, listlessness, and lethargy. Other symptoms can include shaking, twitching, convulsions, low body temperature (under 97.8°F or 36.6°C), and a foul “sweaty feet” odor. If left untreated, the infant can lapse into a coma and die from severe ketoacidosis, hemorrhage, or infections. In the chronic intermittent type, symptoms typically occur within a year after birth and are usually preceded by upper respiratory infections or an increased consumption of protein-rich foods, such as meat and dairy products. Symptoms include vomiting, lethargy, “sweaty feet” odor, acidosis, and ketonuria. Additional symptoms may include diarrhea, thrombocytopenia, neutropenia, or pancytopenia.

There is a wide range of symptoms for 3-methylcrotonglycemia, which can occur in newborns, infants, and young children. These include irritability, drowsiness, unwillingness to eat, vomiting, and rapid breathing. Other symptoms can include hypoglycemia, alopecia, and involuntary body movements.

Approximately 30% of patients with hydroxymethylglutaric acidemia show symptoms within five days after birth and 60% between three and 24 months. Symptoms vary and can include vomiting, deficient muscle tone, lethargy, seizures, metabolic acidosis, hypoglycemia, and hyperammonemia.

Symptoms of methylmalonic acidemia (MA) due to methylmalonyl-CoA mutase (MCoAM) deficiency include lethargy, failure to thrive, vomiting, dehydration, trouble breathing, and deficient muscle tone, and they usually present themselves during infancy. In MA due to N-methyltetrahydrofolate, homocysteine methyltransferase deficiency and high homocysteine levels usually occur during the first two months after birth but have been reported in children as old as 14 years. General symptoms are the same as for MA due to MCoAM but can also include fatigue, delirium, dementia, spasms, and disorders of the spinal cord or bone marrow.

Symptoms of glutaric acidemia type I usually appear within two years after birth and generally become apparent when a minor infection is followed by deficient

muscle tone, seizures, loss of head control, grimacing, and dystonia of the face, tongue, neck, back, arms, and hands. Glutaric acidemia type II symptoms fall into three categories:

- Infants with congenital anomalies present symptoms within the first 24 hours after birth, with symptoms of deficient muscle tone, severe hypoglycemia, hepatomegaly (enlarged liver), metabolic acidosis, and sometimes a “sweaty feet” odor. In some patients, signs include a high forehead, low-set ears, enlarged kidneys, excessive width between the eyes, a mid-face below normal size, and genital anomalies.
- Infants without congenital anomalies have signs of deficient muscle tone, tachypnea (increased breathing rate), metabolic acidosis, hepatomegaly, and a “sweaty feet” odor.
- Mild or later onset symptoms in children include vomiting, hypoglycemia, hepatomegaly, and myopathy (a disorder of muscle or muscle tissue).

There are two types of propionic acidemia, one caused by propionyl-CoA carboxylase (PCoAC) deficiency and the other caused by multiple carboxylase (MC) deficiency. Symptoms of both disorders are generally the same and include vomiting, refusal to eat, lethargy, hypotonia, dehydration, and seizures. Other symptoms may include skin rash, ketoacidosis, irritability, metabolic acidosis, and strong smelling urine commonly described as “tom cats” urine.

There are five types of organic acidemias of fatty acid oxidation that involve deficiencies of acyl-CoA dehydrogenase enzymes: SCAD, MCAD, LCAD, VLCAD, and LCHAD. General symptoms for all five of these disorders include influenza- or cold-like symptoms, hyperammonemia, metabolic acidosis, hyperglycemia, vomiting, a “sweaty feet” odor, and delay in physical development. In young children, other symptoms can include loss of hair, involuntary or uncoordinated muscle movements (ataxia), and a scaly rash (seborrhea rash). Symptoms generally appear between two months and two years of age, but can appear as early as two days after birth up to six years of age.

There are two combined carboxylase deficiency organic acidemias: holocarboxylase synthetase deficiency and biotinidase deficiency. Symptoms of holocarboxylase deficiency include sleep and breathing difficulties, hypotonia, seizures, alopecia, developmental delay, skin rash, metabolic acidosis, ketolactic acidosis, organic aciduria, and hyperammonemia. Symptoms of biotinidase deficiency include seizures, involuntary muscular movements, hypotonia, rapid breathing, developmental delay, hearing loss, and visual problems. Skin

rash, alopecia, metabolic acidosis, organic acidemia, and hyperammonemia can also occur.

Symptoms of beta-ketothiolase deficiency vary. In infants, the most common symptoms include severe metabolic acidosis, ketosis, vomiting, diarrhea (often bloody), and upper respiratory or gastrointestinal infections. Adults with the disorder are usually asymptomatic (showing no outward signs of the disease).

Diagnosis

In all types of organic acidemia, diagnosis cannot be made by simply recognizing the outward appearance of symptoms. Instead, diagnosis is usually made by detecting abnormal levels of organic acid cells in the urine through a urinalysis. The specific test used is called combined gas chromatography-mass spectrometry. In gas chromatography, a sample is vaporized and its components separated and identified. Mass spectrometry electronically weighs molecules. Every molecule has a unique weight (or mass). In newborn screening, mass spectrometry analyzes blood to identify what amino acids and fatty acids are present and the amount present. The results can identify if the person tested has a specific organic acidemia. Many organic acidemias also can be diagnosed in the uterus by using an enzyme assay of cultured cells, or by demonstrating abnormal organic acids in the fluid surrounding the fetus. In some laboratories, analysis is done on blood, skin, liver, or muscle tissue. Molecular DNA testing is also available for common mutations of MCAD and LCHAD.

Since most organic acidemias are rare, routine screening of fetuses or newborns is not usually done and is not widely available. In MCAD, a more common organic acidemia, abnormal organic acids are excreted in the urine intermittently so a diagnosis is made by detecting the compound phenylpropionylglycine in the urine.

Treatment and management

There are few medications available to treat organic acidemias. The primary treatments are dietary restrictions tailored to each disorder, primarily restrictions on the intake of certain amino acids. For example, patients with some acidemias, such as isovaleric and beta-ketothiolase deficiency, must restrict their intake of leucine by cutting back on foods high in protein. Patients with propionic or methylmalonic acidemias must restrict their intake of threonine, valine, methionine, and isoleucine. The intake of the restricted amino acids is based on the percentage of lean body mass rather than body weight. Some patients also benefit from growth hormones. Patients with combined carboxylase deficiency are sometimes treated with

large doses of biotin. Some patients with methylmalonic acidemia are treated with large doses of vitamin B12.

Glucose infusion (to provide calories and reduce the destructive metabolism of proteins) and bicarbonate infusion (to control acidosis) are often used to treat acute episodes of some acidemias, including isovaleric, 3-methylcrotonylglycemia, and hydroxymethylglutaric.

The primary treatment for MCAD is to not go without food for more than 10 or 12 hours. Children should eat foods high in carbohydrates, such as pasta, rice, cereal, and non-diet drinks, when they are ill. A low fat diet is also recommended. The drug L-carnitine is sometimes used by physicians to prevent low blood sugar when patients have infections or are not eating regularly.

The treatment of LCHAD is similar to that of MCAD, except that L-carnitine is usually not prescribed. Children with LCHAD are often treated with medium chain triglycerides oil.

Holocarboxylase synthetase deficiency is generally treated by administering 10 milligrams (mg) of biotin daily. Eating large amounts of yeast, liver, and egg yolks, which naturally contain biotin, did not improve the condition. Biotinidase deficiency is usually treated successfully with pharmacological doses of between 5 and 20 mg of biotin daily. However, hearing and vision problems appear to be less reversible.

Prognosis

The prognosis of patients with organic acidemias varies with each disorder and usually depends on how quickly and accurately the condition is diagnosed and treated. Some patients with organic acidemias are incorrectly diagnosed with other conditions, such as sudden infant death syndrome (SIDS) or Reye syndrome. Without a quick and accurate diagnosis, the survival rate decreases with each episode of the disorder. Death occurs within the first few years of life, often within the first few months. With a quick diagnosis and aggressive monitoring and treatment, patients can often live relatively normal lives. For example, children with either biotinidase deficiency or holocarboxylase synthetase deficiency, when detected early and treated with biotin, have generally shown resolution of the clinical symptoms and biochemical abnormalities.

Ornithine transcarbamylase deficiency

Definition

Ornithine transcarbamylase deficiency is a disorder in which the body fails to properly process ammonia, which can lead to coma and death if left untreated.

Description

Persons with ornithine transcarbamylase deficiency (OTC deficiency) have a problem with nitrogen metabolism. Too much nitrogen in the blood in the form of ammonia can cause brain damage, coma, and death. Ammonia is made up of nitrogen and hydrogen. Ammonia found in humans mostly comes from the breakdown of protein—either protein broken down from muscles, organs, and tissues already in the body, or excess protein that is eaten in the diet. Since excess ammonia is harmful, it is immediately excreted in normal humans after passing through the urea cycle and becoming urea. *Ornithine transcarbamylase* is a gene involved in the urea cycle—the process of making ammonia into urea, which occurs in the liver.

It is important to make urea, because unlike ammonia, urea can be excreted by the kidney into the urine. Ammonia, on the other hand, cannot be effectively excreted by the kidney. So, if the *ornithine transcarbamylase* (OTC) function is reduced or impaired, ammonia builds up in the bloodstream. This buildup of ammonia in the bloodstream can lead to consequences as severe as coma and death. The amount of ammonia found in the bloodstream, and the severity of the disorder, depend on how well the OTC gene functions. If it functions reasonably well, the person should have a minor form of the disorder or no disorder. If the gene functions extremely poorly, or not at all, the disorder will be severe.

Synonyms for ornithine transcarbamylase deficiency include hyperammonemia type II, ornithine carbamyl transferase deficiency, OTC deficiency, UCE, urea cycle disorder, OTC Type, and hyperammonemia due to ornithine transcarbamylase deficiency.

Genetic profile

OTC deficiency is an X-linked recessive disorder. This means that it is found on the X chromosome (specifically, it is located on the short arm at Xp21.1). Recessive disorders require that only abnormal genes, and no normal genes, be present. For non-sex chromosomes, this means that both copies of a gene (one received from each parent) must be abnormal in order for that person to have the disorder.

In X-linked recessive disorders, however, only one abnormal copy of a gene must be present to cause the disorder in males. Males possess only one X chromosome, from their mother, and one Y chromosome, which they receive from their father. If the mother is a carrier for the disorder (she has one normal gene and one abnormal gene), a male child would have a 50% chance of receiving an abnormal gene from her. If he receives the abnormal gene, he will have the disorder.

A female child of a female carrier is much less likely to have the disorder. Unless the father has OTC deficiency, a female child will have one normal and one abnormal gene. Since recessive disorders require that both genes be mutated, the female child cannot have the disorder. Females with only one mutant OTC gene may have a mild form of the disorder because it is not purely recessive. Usually, the normal copy of the gene can sufficiently compensate for the poor functioning of the second, abnormal gene.

Some females do have the full-blown disorder, probably because of a phenomenon called X-inactivation. Although females have two X chromosomes in each cell, only one is active. Therefore, it is possible a female could have the disorder because only the abnormal gene was

active in each cell of the liver, which is where OTC function takes place. Not enough is known about X-inactivation to speculate on the likelihood of this occurring. OTC disease due to X-inactivation is not very common.

If the father has the gene for the disorder, he cannot pass it on to his male child (he does not give the male child an X chromosome, only a Y). He can give his female child one copy of the gene, which might result in a mild form of the disorder or the full-blown disorder due to X-inactivation.

Demographics

OTC affects infants at the rate of approximately 1 birth in every 70,000. As expected with an X-linked disorder, the disorder is more common in males.

Signs and symptoms

Before birth there are no symptoms of OTC deficiency because the exchange of nutrients and fluids between the mother and fetus allows the excess ammonia to leave the infant's blood and go into the mother's blood. The mother is then able to get rid of the ammonia as urea because she either lacks the disorder or her ammonia levels are medically well-controlled.

The most severe cases of OTC deficiency usually present in infants before they are a week old, typically in males. It may take several days for symptoms to appear, since it takes that long for protein, and therefore ammonia levels, to build up in the infant. Affected infants generally show periods of inactivity, a failure to feed, and vomiting. Unfortunately, many other disorders may also present with these same general symptoms, and new parents may not recognize these as abnormal in an infant. These symptoms are always accompanied in OTC deficiency by hyperammonemia, or high levels of ammonia in the blood.

Hyperammonemia is the most important symptom for identification and treatment of ornithine transcarbamylase deficiency. It is the cause of all other symptoms seen in OTC deficiency. Additionally, hepatomegaly (an enlarged liver) and seizures may also be present. If the disorder, or at least the hyperammonemia, is not recognized and treated, the symptoms may progress into coma and eventually death. A failure to quickly resolve the hyperammonemia once an infant lapses into a coma may also lead to severe intellectual disability or death.

Patients with milder forms of the disorder may show symptoms later in life such as failure to grow at a normal rate or they may experience developmental delay. Developmental delay is an inability to reach recognized

milestones like speaking or grasping objects at an appropriate age. These milder symptoms would be accompanied by hyperammonemia, but the levels of ammonia would be much lower than in an episodic attack of hyperammonemia or in the severely ill infant. Other persons with mild forms of the disorder may have no symptoms, or may only experience nausea after a meal with large protein content.

Persons with a mild form of the disorder and no other symptoms may also learn they have the disorder from an episode of acute hyperammonemia. Acute conditions are brief and immediate, whereas chronic conditions are long-lasting.

An episodic attack of acute hyperammonemia, then, is an episode where levels of ammonia climb above what may be already high levels of ammonia. A person with an episode of acute hyperammonemia can have symptoms including some, or all, of the following: vomiting, lack of appetite, drowsiness, hepatomegaly, seizures, coma, and death. These episodes can be life-threatening and may require hospitalization depending on their severity and response to medication.

These episodic attacks are probably related to a large increase in the amount of protein being broken down in the body, which results in too much ammonia being produced. This ammonia cannot be immediately excreted, which results in hyperammonemia. The most common reasons for a change in the amount of protein broken down are probably starvation, illness, and surgery. Even persons with no previous symptoms can experience a fatal episode of acute hyperammonemia brought on by an increase in protein breakdown. Since an episodic attack of hyperammonemia can be fatal without any previous symptoms, persons who have at least one family member with OTC deficiency should consider testing to determine whether they have the gene for the disorder. If the disorder is known to be present, an episode of hyperammonemia might be anticipated and its effect lessened.

Diagnosis

A definitive diagnosis of OTC deficiency is made via laboratory testing, since physical symptoms are very general and common to a large number of disorders. A high level of ammonia in the blood is the hallmark of this disorder and other disorders that affect the urea cycle. In the short term, the levels of two amino acids in the urine, orotate and citrulline, should distinguish between OTC deficiency and other urea cycle deficiencies. In OTC deficiency, citrulline levels are normal or low, and orotate levels are usually high. In the long term, however, the most definitive diagnosis can be made through DNA

analysis, or through a test of OTC activity in a small piece of liver tissue (a biopsy) taken from the patient.

Prenatal diagnosis of the disorder is difficult and not indicated unless there is an affected family member with the disorder. In that case, if the mutation is known, DNA analysis would reveal the same mutation as in the family member with OTC deficiency. If the mutation is not known, a method called linkage analysis may be used. In linkage analysis, the OTC gene itself is not analyzed, but the DNA near the gene is analyzed. The “near DNA” can then be compared to the “near DNA” of the affected family member. If the DNAs are different, then the fetus should not have the disorder. If they are the same, then the fetus probably has the disorder.

Treatment and management

Long-term management

The severity of the disorder is the most important factor in determining long-term treatment of OTC deficiency. Individuals most severely affected by OTC deficiency, usually infant males, should have liver transplants. As previously mentioned, the urea cycle and OTC functions occur in the liver. The transplantation immediately corrects OTC deficiency. Episodes of life-threatening ammonemia are prevented, although monitoring of tissue levels of ammonia is suggested. Another important benefit is that the transplant allows the child to develop and grow in a normal manner, without the threat of developmental delay or intellectual disability. Transplants are now recommended even for children less than one year of age with a severe form of the disorder.

Two problems with liver transplants exist, however. First, it is difficult to obtain a liver from among the limited supply of donors, especially if the child is not currently hospitalized. The second problem arises from the way in which organs are assigned. Persons who are critically ill receive priority in organ donor lists. This means children whose disease is manageable may not be able to receive a transplant.

Second, children with transplants must have their immune system suppressed. The immune system fights off and lets one recover from infections like colds, flu, and chicken pox. However, it also fights the introduction of an organ from someone else's body, even a relative—except identical twins. Thus, as long as a person has a transplant, that person must have their immune system suppressed so that the transplanted organ is not killed by the body it is in. The problem with immune suppression is that a person is much more likely to become sick. This disadvantage is far outweighed by the advantages of normal mental development and the prevention of death in patients with severe OTC deficiency.

KEY TERMS

Developmental delay—When children do not reach certain milestones at appropriate ages. For example, a child should be able to speak by the time he or she is five years old.

Hyperammonemia—An excess of ammonia in the blood.

Urea—A nitrogen-containing compound that can be excreted through the kidney.

Urea cycle—A series of complex biochemical reactions that remove nitrogen from the blood so ammonia does not accumulate.

Patients in rural areas, or areas where there is no immediate access to a hospital equipped to care for a patient with an acute attack of hyperammonemia, should also be strongly considered for a liver transplant if the patient is predisposed to attacks of life-threatening hyperammonemia.

For less severely affected children, or children unable to obtain a liver transplant, long-term therapy consists of a combination of drugs, usually oral; sodium phenylbutyrate; and diet. This bypasses the normal process of the breakdown of protein into urea in the liver, which is the usual way that ammonia leaves the body. Children with OTC deficiency are placed on a low-protein diet so their protein breakdown system does not become overwhelmed and lead to hyperammonemia. Children with OTC deficiency are also given arginine, an amino acid, which, for reasons that are unclear, causes more nitrogen, which is part of ammonia, to be excreted in the urine, and lowers blood ammonia. Dietary regimens vary from patient to patient based on their age, size, and the severity of the disorder. A nutrition expert must be consulted when developing an appropriate diet. The strictest diet consists of vitamin supplements and no protein other than essential amino acids. Essential amino acids are those that cannot be made by the body and must be obtained through food. Since proteins are made up of amino acids, and only amino acids, that means this diet is extremely restrictive. It also means that very little ammonia is left in the bloodstream since most of the otherwise free ammonia is tied up in the synthesis of the non-essential amino acids, amino acids made by the body itself.

Any chronic disease is stressful for a family. Parents and patients should consider support and information groups like the National Urea Cycle Disorders Foundation.

Short-term management

Short-term management of attacks of crisis hyperammonemia (severe acute hyperammonemia) consists of dialysis and drug therapy. Dialysis and large doses of the drugs sodium benzoate and sodium phenylacetate and doses of arginine are used to decrease the levels of ammonia in the blood. These methods are used together due to their synergistic effect.

Dialysis is a process where a toxic substance is removed from the blood. This can best be understood by pouring a small amount of cola into a glass. Now pour a large amount of water into it. In this way, the cola is “watered down” or diluted. Ammonia is diluted in a similar way using dialysis. Blood is removed from a patient and run through a hose. At one point, this hose runs through a tank made up of liquid that contains all the components of blood, but no ammonia (this liquid is like the water in the water and cola example). Thus, ammonia spreads throughout the blood and the liquid surrounding the hose (the same way cola will spread throughout water added to the glass) and the amount of ammonia in the blood is reduced. By continuously pumping blood through the hose and changing the liquid around the hose, most of the ammonia can be removed from the blood. All of the really large particles, like red blood cells, are also kept in the blood because the hose has holes that are only large enough to let smaller particles like ammonia out while keeping red blood cells in.

The future

The future treatment of OTC deficiency will likely come from experiments in gene therapy. OTC deficiency is a disorder particularly amenable to gene therapy because only one gene is affected and only one organ, the liver, would need the new gene. However, gene therapy has not been successfully demonstrated in human beings. Many technical problems must still be solved in order to successfully treat OTC deficiency and other disorders like it with gene therapy.

Prognosis

Only 50% of the most severely affected patients live beyond the time they first attend school. Of those receiving liver transplants, 82% of patients survive five years after receiving the transplant. Children with the severe disorder that receive drug therapy are much more likely to experience intellectual disability, developmental delay, and a lack of growth. Also, many infants who experience hyperammonemic comas have severe mental damage.

For individuals not identified at birth or soon after, the prognosis varies widely. The consequences of the disorder are affected by the severity of the disorder and how

it is managed, although anyone with the disorder may experience life-threatening attacks of acute hyperammonemia. In terms of long-term survival, puberty appears to be a difficult time for those with OTC deficiency, and persons who survive until after puberty have improved outcomes. The prognosis for this disorder can vary from quite hopeful to very distressing based upon its severity and how well the disorder can be controlled. A severe disorder that is well controlled may still have a positive outcome.

Osteoarthritis

Definition

Osteoarthritis is a degenerative joint disease characterized by the breakdown of the joint's cartilage.

Description

Osteoarthritis is a degenerative joint disease and one of the oldest, most common types of arthritis. It is characterized by the breakdown of cartilage, which can allow bones to rub against each other, causing pain and loss of movement. Often called "wear-and-tear arthritis,"

Illustration showing an advanced case of osteoarthritis in a knee joint. (BSIP/Science Source)

osteoarthritis can be caused by injury, abnormal growth, and inherited factors.

The biological causes of the disorder are currently unknown; however, osteoarthritis is thought to be due to mechanical stress and chronic, low-grade inflammation in joints. As osteoarthritis progresses, the collagen matrix becomes disorganized and begins to break down, allowing for both decreased support of the joints and increased inflammation at the joints.

In many cases, certain conditions seem to trigger osteoarthritis. People with joint injuries from sports, work-related activity, or accidents may be at increased risk, and obesity may lead to osteoarthritis of the knees and other weight-bearing joints. Individuals with mismatched surfaces on the joints that could be damaged over time by abnormal stress may be prone to osteoarthritis.

As collagen and cartilage are lost, tendons may thicken to compensate at bone and muscle junctions, which can lead to stiffness and pain associated with the disease. New bone outgrowths, or "spurs," can form at the periphery of joints to improve the congruence of joint surfaces in the absence of normal cartilage support.

Demographics

Osteoarthritis is the most common form of arthritis. It is estimated to affect more than 32.5 million Americans, mostly after age 45. Women are more commonly affected than men.

In the United States, 13.5% of men and 18.7% of women older than 45 have osteoarthritis of the knee and more than 3% of adults 45 and older have osteoarthritis of the hip. Prevalence of osteoarthritis in most joints is higher in men than women under age 50. After that age, more women are affected by osteoarthritis, and the occurrence of the disease increases with age. In men, the hip is affected more often, while in women, the hands, fingers, and knees are more problematic.

Some forms of osteoarthritis are more prevalent in African American men and women than in Caucasians, possibly because they tend to have a higher bone mineral density. In the case of knee osteoarthritis, it may be related to occupational and physical demands. African American women also have a higher risk of developing bilateral knee osteoarthritis and hip osteoarthritis, compared to women of other races.

Osteoarthritis is common worldwide, although the risk varies among ethnic groups. Caucasians have a higher risk than Asians, and the risk of osteoarthritis in the hips is lower in Asia and some Middle East countries than in the United States. Asians appear to have a higher incidence of osteoarthritis in the knees than Caucasians do, but an equal risk in the spine. Location of affected joints and inherited forms of the disorder can influence the age of onset.

Genetic profile

Genetics play a role in the development of osteoarthritis, particularly in the hands and hips. One study found that heredity might be involved in 30% of people with osteoarthritic hands and in 65% of those with osteoarthritic knees. Another study found a higher correlation of osteoarthritis between parents and children, and between siblings, than between spouses. Other research has shown that a genetic abnormality may promote a breakdown in the protective structure of cartilage.

Abnormal collagen genes have been identified in some families with osteoarthritis. One recent study found that the type IX collagen gene (*COL9A1*) located on chromosome 6 might be a susceptibility locus for female hip osteoarthritis. Other research has suggested that mutations in the *COL2A1* gene may be associated with osteoarthritis. While there is some evidence of other genetic factors in the development of osteoarthritis, the heritability and genes involved are not well documented.

A 2021 review reported new insights into the way genetics affect bone mass. Although bone mineral density is typically associated with osteoporosis, investigators also found a link between bone mineral density and the risk of developing osteoarthritis. They found genetic

markers suggesting that low bone mass combines with other factors to develop osteoarthritis.

Because osteoarthritis follows a complex disease process, further understanding of genes related to bone mass and other risk factors can help better understand how these genetic factors interact with other causes, such as obesity. As many as 86 genetic loci might be associated with inheritance of osteoarthritis risk. Current study includes determining which genes might play a protective role in the disease. As of 2021, multiple studies were under way to look at genomics, genetics, and epigenetics of osteoarthritis, as well as the role of specific genes. These more recent studies are beginning to connect genetic information with risk factors to determine how the genes affect development. These efforts eventually can lead to appropriate, even targeted, interventions.

Signs and symptoms

Although up to 85% of people over 65 show evidence of osteoarthritis on x-ray, only 35%–50% experience symptoms. Symptoms range from very mild to very severe and can affect the hands and weight-bearing joints such as knees, hips, feet, and the back. The pain of osteoarthritis usually begins gradually and progresses slowly over many years.

Osteoarthritis is commonly identified by aching pain in one or more joints, stiffness, and loss of mobility. The disease can cause significant trouble walking and stair-climbing. Inflammation may or may not be present.

Illustration of a healthy joint (left) and one affected by osteoarthritis (right). (Designua/Shutterstock)

KEY TERMS

Cartilage—Supportive connective tissue that cushions bone at joints or connects muscle to bone.

Collagen—The main supportive protein of cartilage, connective tissue, tendon, skin, and bone.

Corticosteroids—Anti-inflammatory medications. They are related to cortisol, a naturally produced hormone that controls many bodily functions.

Extensive use of the joint(s) often exacerbates pain there. Osteoarthritis is often more bothersome at night than in the morning, and in humid weather rather than dry weather. Periods of inactivity, such as sleeping or sitting, may result in stiffness, which can be eased by stretching and exercise.

Bony lumps on the end joint of the finger, called Heberden's nodes, and on the middle joint of the finger, called Bouchard's nodes, may also develop, and collagen support at the joints is depleted.

Diagnosis

A diagnosis of osteoarthritis is made based on a physical exam and history of symptoms.

X-rays are used to confirm the diagnosis. In people over age 60, the disease can often be observed on x-ray. An indication of cartilage loss arises if the normal space between the bones in a joint is narrowed, if there is an abnormal increase in bone density, or if bony projections or erosions are evident. Any cysts that might develop in osteoarthritic joints are also detectable by x-ray.

Additional tests can be performed if other conditions are suspected or if the diagnosis is uncertain. Blood tests can rule out rheumatoid arthritis or other forms of arthritis.

It is possible to distinguish osteoarthritis from other joint diseases by considering a number of factors together:

- Osteoarthritis usually occurs in older people.
- It is usually located in only one or a few joints.
- The joints are less inflamed than in other arthritic conditions.
- Progression of pain is almost always gradual.
- A few of the most common disorders that might be confused with osteoarthritis are rheumatoid arthritis, chondrocalcinosis, and Charcot's joints.

Treatment and management

There is no known way to prevent osteoarthritis or slow its progression. Some lifestyle changes can reduce or delay symptoms, but treatment often focuses on decreasing pain and improving joint movement. Prevention and treatment measures may include the following:

- Exercises to maintain joint flexibility and improve muscle strength. By strengthening the supporting muscles, tendons, and ligaments, regular weight-bearing exercise helps protect joints, even possibly stimulating growth of the cartilage.
- Joint protection, which prevents strain and stress on painful joints.
- Heat/cold therapy for temporary pain relief.
- Various pain-control medications including corticosteroids and NSAIDs (nonsteroidal anti-inflammatory drugs, such as aspirin, ibuprofen, and naproxen). For inflamed joints that are not responsive to NSAIDs, injectable glucocorticoids may be used. For mild pain without inflammation, acetaminophen may be used.
- Weight control can prevent extra stress on weight-bearing joints. One study reported that weight loss seemed to reduce the risk for symptomatic osteoarthritis of the knee in women; in another study, women who lost 11 pounds or more cut their risk for developing osteoarthritis in half.
- Surgery may be needed to relieve chronic pain in damaged joints. Osteoarthritis is the most common indication for total joint replacement of the hip and knee.

New treatment findings

Studies have found that estrogen may promote healthy joints in women. Hormone replacement therapy may significantly reduce the risk in postmenopausal women, particularly in the knees.

It has been reported that deficiencies in vitamin D in older people may worsen their condition, so individuals with osteoarthritis should strive to take the recommended 400 IU per day. To protect bones, adults should also consume at least 1,000 mg of calcium daily.

Glucosamine and chondroitin sulfate are popular nutritional supplements that may diminish the symptoms of osteoarthritis. According to some reports, a daily dose of 750–1,500 mg of glucosamine and chondroitin sulfate may reduce joint pain, stiffness, and swelling; however, these supplements are not approved by the Food and Drug Administration as effective treatment of osteoarthritis. A person with osteoarthritis should consult with a doctor before using dietary supplements to treat symptoms.

QUESTIONS TO ASK YOUR DOCTOR

- Please describe the bodily changes that take place as a result of osteoarthritis.
- Why is osteoarthritis considered a genetic disorder?
- Is there a way to prevent developing osteoarthritis?
- How is osteoarthritis likely to affect my quality of life?

Prognosis

Osteoarthritis is not life-threatening, but quality of life can deteriorate significantly due to the pain and loss of mobility that it causes. Advanced osteoarthritis can force the patient to forgo activities, even walking, unless the condition is alleviated by medication or corrected by surgery.

There is no cure for osteoarthritis, and no treatment alters its progression with any certainty. Only heart disease has a greater impact on work, and 5% of those who leave the workforce do so because of osteoarthritis.

Osteogenesis imperfecta

Definition

Osteogenesis imperfecta (OI) is a group of genetic diseases of collagen in which the bones are formed improperly, making them fragile and prone to breaking.

Description

Collagen is a fibrous protein material. It serves as the structural foundation of skin, bone, cartilage, and ligaments. In osteogenesis imperfecta, the collagen produced is abnormal and disorganized. This results in a number of abnormalities throughout the body, the most notable being fragile, easily broken bones. Another cardinal sign of OI is a blue-grey tint to the sclera of the eye, which otherwise is normally white.

There are eight forms of OI, types I through VIII. Of these, type II is the most severe and is usually fatal within a short time after birth. Most types have some overlapping and some distinctive symptoms, particularly weak bones.

Genetic profile

Evidence suggests that OI results from mutations in the *COL1A1*, *COL1A2*, *CRTAP*, and *P3H1* genes. Some studies note additional mutations in genes *EPRE1* and *FKBP10* being responsible for OI. Mutations in the *COL1A1* gene, located on 17q21.3–q22.1, and in *COL1A2*, located on 7q22.1, are responsible for more than 90% of all cases of OI. These two genes provide instructions for making proteins that are used to assemble type I collagen, the most abundant protein in bone, skin,

Illustration of a healthy bone (left) and one made brittle by osteogenesis imperfecta. (joshya/Shutterstock)

and other connective tissues. *COL1A1* and *COL1A2* gene mutations are due to an autosomal dominant pattern of inheritance and are responsible for OI types I–VI. The *CRTAP* gene, located on 3p22.3, provides instructions for making a protein called “cartilage associated protein,” required for normal bone development. Mutations in the *CRTAP* gene are responsible for type VII and are inherited in an autosomal recessive pattern. The *P3H1* gene, located on 1p34.1, instructs the making of the enzyme prolyl-3 hydroxylase 1, which modifies proline, an amino acid that is critical for the normal folding and assembly of collagen as it is being made. If the collagen molecule is not formed correctly due to the lack of or improper function of this enzyme, the function of the collagen will not be correct, leading to connective tissue abnormalities as seen in OI, particularly type VIII. Mutations in the *P3H1* gene, like mutations in the *CRTAP* gene, are inherited in an autosomal recessive pattern.

OI is usually inherited as an autosomal dominant condition, and 90% of OI cases are due to a mutation in the *COL1A1* or *COL1A2* genes. In autosomal dominant inheritance, a single abnormal gene on one of the autosomal chromosomes (one of the first 22 “nonsex” chromosomes) from either parent can cause the disease. One of the parents will have the disease (since it is dominant) and is the carrier. Only one parent needs to be a carrier in order for the child to inherit the disease. A child who has one parent with the disease has a 50% chance of also being a carrier and a 50% chance of not inheriting the dominant gene and, thus, not having the disorder.

In OI, the genetic abnormality may direct cells to make an altered collagen protein, and the presence of this altered

collagen causes OI types II, III, or IV. Alternately, the dominant altered gene may fail to direct cells to make any collagen protein. Although some collagen is produced by instructions from the normal gene, an overall decrease in the total amount of collagen produced results in OI type I.

If both parents have OI caused by an autosomal dominant gene change, there is a 75% chance that the child will inherit one or both OI genes. In other words, there is a 25% chance the child will inherit only the mother’s OI gene (and the father’s unaffected gene), a 25% chance the child will inherit only the father’s OI gene (and the mother’s unaffected gene), and a 25% chance the child will inherit both parents’ OI genes. Because this situation is uncommon, the outcome of a child inheriting two OI genes is hard to predict. It is likely that the child would have a severe, possibly lethal, form of the disorder.

About 25% of children with OI are born into a family with no history of the disorder. This occurs when the *COL1A1* or *COL1A2* gene spontaneously mutates in either the sperm or the egg before the child’s conception. No triggers for this type of mutation are known. This is called a new dominant mutation. This is most common in the more severe types of OI such as type II or type III. The affected child has a 50% chance of passing the disorder on to his or her children. In most cases, when a family with no history of OI has a child with OI, they are not at greater risk than the general population for having a second child with OI, and unaffected siblings of a person with OI are at no greater risk of having children with OI than the general population.

In studies of families into which infants with OI type II were born, most of the babies had a new dominant

mutation in a collagen gene. In some of these families, however, more than one infant was born with OI. Previously, researchers had seen this recurrence as evidence of recessive inheritance of this form of OI. More recently, however, researchers have concluded that the rare recurrence of OI to a couple with a child with autosomal dominant OI is more likely due to gonadal mosaicism. Instead of a mutation occurring in an individual sperm or egg, it occurs in a percentage of the cells that give rise to a parent's multiple sperm or eggs. This mutation, present in a percentage of the person's reproductive cells, can result in more than one affected child without affecting the parent with the disorder. An estimated 2%–4% of families into which an infant with OI type II is born are at risk of having another affected child because of gonadal mosaicism.

Demographics

The prevalence of OI was reported to be 6 to 7 in 100,000 people worldwide in 2015, with types I and IV being the most commonly seen out of the eight types, with a prevalence of 4 to 5 in 100,000 people.

Signs and symptoms

Type I

This is the most common and mildest type. Among the common features of type I are the following:

- Bones are predisposed to fracture, with most fractures occurring before puberty. People with OI type I typically have about 20–40 fractures before puberty.
- Stature is normal or near normal.
- Joints are loose, and muscle tone is low.
- Usually sclera (whites of the eyes) have a blue, purple, or gray tint.
- Face shape is triangular.
- There is a tendency toward scoliosis (a curvature of the spine).
- Bone deformity is absent or minimal.
- Dentinogenesis imperfecta may occur, causing brittle teeth.
- Hearing loss is a possible symptom, often beginning in the early 20s or 30s.
- Structure of collagen is normal, but the amount is less than normal.

Type II

Sometimes called the lethal form, type II is the most severe form of OI. Among the common features of Type II are the following:

- Frequently, OI type II is lethal at or shortly after birth, often as a result of respiratory problems.
- Fractures are numerous, and bone deformity is severe.
- Stature is small with underdeveloped lungs.
- Collagen is formed improperly.

Type III

Among the common features of type III are the following:

- Bones fracture easily. Fractures are often present at birth, and x-rays may reveal healed fractures that occurred before birth. People with OI type III may have more than 100 fractures before puberty.
- Stature is significantly shorter than normal.
- Sclera (whites of the eyes) have a blue, purple, or gray tint.
- Joints are loose, and muscle development is poor in arms and legs.
- Rib cage is barrel-shaped.
- Face shape is triangular.
- Scoliosis (a curvature of the spine) is present.
- Respiratory problems are possible.
- Bones are deformed, and deformity is often severe.
- Dentinogenesis imperfecta may occur, causing brittle teeth.
- Hearing loss is possible.
- Collagen is formed improperly.

Type IV

OI type IV falls between type I and type III in severity. Among the common features of type IV are the following:

- Bones fracture easily, with most fractures occurring before puberty.
- Stature is shorter than average.
- Sclera (whites of the eyes) are normal in color, appearing white or near white.
- Bone deformity is mild to moderate.
- Scoliosis (curvature of the spine) is likely.
- Rib cage is barrel-shaped.
- Face is triangular in shape.
- Dentinogenesis imperfecta may occur, causing brittle teeth.
- Hearing loss is possible.
- Collagen is formed improperly.

KEY TERMS

Collagen—The main supportive protein of cartilage, connective tissue, tendon, skin, and bone.

Ligament—A type of connective tissue that connects bones or cartilage and provides support and strength to joints.

Mutation—An inherited or *de novo* change in the DNA sequence of the genome.

Sclera—The tough white membrane that forms the outer layer of the eyeball.

Scoliosis—Abnormal curvature of the spine, usually defined as greater than ten degrees to the right or left as the doctor faces the patient.

Diagnosis

It is often possible to diagnose OI solely on clinical features and x-ray findings. Collagen or DNA tests may help confirm a diagnosis of OI. These tests generally require several weeks before results are known. Approximately 10%–15% of individuals with mild OI who have collagen testing, and approximately 5% of those who have genetic testing, test negative for OI despite having the disorder.

Diagnosis is usually suspected when a baby has bone fractures after having suffered no apparent injury. Another indication is small, irregular, isolated bones in the sutures between the bones of the skull (Wormian bones). Sometimes the bluish sclera serves as a diagnostic clue. Unfortunately, because of the unusual nature of the fractures occurring in a baby who cannot yet move, some parents have been accused of child abuse before the actual diagnosis of OI was reached.

Prenatal diagnosis

Testing is available to assist in prenatal diagnosis. Women with OI who become pregnant, or women who conceive a child with a man who has OI, may wish to explore prenatal diagnosis. Due to the wide range of potential mutations within a large genome, sequencing has been difficult for the detection of OI. With an increase in technology and the use of newer sequencing methods such as whole genome sequencing, next generation sequencing, and resequencing arrays, prenatal genetic testing is becoming more and more accurate. Because of the relatively small risk (2%–4%) of recurrence of OI type II in a family, families may opt for ultrasound studies to determine if a developing fetus has the disorder.

Ultrasound is the least invasive procedure for prenatal diagnosis and carries the least risk. Using ultrasound, a doctor can examine the fetus's skeleton for bowing of the leg or arm bones, fractures, shortening, or other bone abnormalities that may indicate OI. Different forms of OI may be detected by ultrasound in the second trimester. The reality is that when it occurs as a new dominant mutation, it is found inadvertently on ultrasound, and it may be difficult to know the diagnosis until after delivery since other genetic conditions can cause bowing and/or fractures prenatally.

Chorionic villus sampling is a procedure to obtain chorionic villi tissue for testing. Examination of fetal collagen proteins in the tissue can reveal information about the quantitative or qualitative collagen changes that lead to OI. When a parent has OI, it is necessary for him or her to have the results of a collagen test available. Chorionic villus sampling can be performed at 10–12 weeks of pregnancy.

Amniocentesis is a procedure that involves inserting a thin needle into the amniotic sac in the uterus and withdrawing a small amount of amniotic fluid. DNA can be extracted from the fetal cells contained in the amniotic fluid and tested for the specific mutation known to cause OI in a particular family. This technique is useful only when the mutation causing OI in a particular family has been identified through previous genetic testing of affected family members, including previous pregnancies involving a baby with OI. Amniocentesis is performed at 16–18 weeks of pregnancy.

Treatment and management

There are no treatments available to cure OI, nor to prevent most of its complications. Most treatments are aimed at correcting the fractures and bone abnormalities caused by OI. Splints, casts, braces, and rods are all used. Rodding refers to a surgical procedure in which a metal rod is implanted within a bone (usually the long bones of the thigh and leg). This is done when bowing or repeated fractures of these bones have interfered with a child's ability to begin to walk. Physical therapy and occupational therapy is also used for the treatment and management of OI to increase mobility and decrease muscle weakness and muscle wasting.

Medications have been evaluated for their potential use to treat OI. These include growth hormone treatment, treatment with intravenous and oral drugs called bisphosphonates, an injected drug called teriparatide (for adults only), and gene therapies. This type of pharmaceutical treatment has been shown to decrease the number of bone fractures and the frequency and intensity of pain.

Other treatments include hearing aids and early capping of teeth. Patients may require the use of a walker or wheelchair. Pain may be treated with a variety of medications. Exercise is encouraged as a means to promote muscle and bone strength. Swimming is a form of exercise that puts a minimal amount of strain on muscles, joints, and bones. Walking is encouraged for those who are able.

Smoking, excessive alcohol and caffeine consumption, and steroid medications may deplete bone and increase bone fragility.

Alternative treatments such as acupuncture, naturopathic therapies, hypnosis, relaxation training, visual imagery, and biofeedback have all been used to try to decrease the constant pain of fractures.

Prognosis

Lifespan for people with OI types I, III, and IV is not generally shortened. The prognosis for people with these types of OI is quite variable, depending on the severity of the disorder and the number and severity of the fractures and bony abnormalities.

Fifty percent of all babies with OI type II are still-born. The rest of these babies usually die within a very short time after birth. In recent years, some people with type II have lived into young adulthood.

Osteoporosis

Definition

Osteoporosis is a disease characterized by low bone mass and deterioration of bone tissues, leading to bone fragility and, consequently, an increase in fracture risk.

Description

The term "osteoporosis" comes from the Greek words "osteon," "meaning bone," and "porus," meaning "pore" or "passage." Osteoporosis literally makes bones porous. The amount of calcium stored in bones decreases over time, causing the skeleton to weaken.

In the bodies of younger adults, both the mineral portion and the framework of bone is in constant flux. Old tissue is broken down and reabsorbed, and new bone is created at approximately the same rate. In later years, this rate of renewal begins to slow behind the rate of removal. This slowing is what leaves the bones thinner and more fragile. The most typical sites of fractures related to osteoporosis are the hips, spine, wrists, and ribs, although the disease can affect any bone in the body.

The average woman acquires 98% of her skeletal mass by approximately age 20. Building strong bones during childhood and adolescence is a key defense against developing osteoporosis later. There are four main steps to preventing osteoporosis: consuming a balanced diet rich in calcium and vitamin D; participating in weight-bearing exercise; following a healthy lifestyle, including no smoking and limited alcohol intake; and testing bone density and taking medication when appropriate.

In compact bone, which forms the long bones of the body, concentric circles of bony material surround large channels that contain blood vessels, lymph vessels, and nerves. The sturdy but normally porous structure of a healthy bone can be weakened and leached away if its calcium content is not maintained. (Dee Breger/Science Source)

Type I, postmenopausal osteoporosis, is the most common. It is usually a consequence of reproductive hormone deficiency, and it afflicts mostly women over age 50. The disorder typically appears within the first 10 or 20 years after menopause.

Men may also develop the disorder, usually around 50 to 60 years of age, as a result of the following:

- Prolonged exposure to certain medications such as steroids used to treat asthma or arthritis, anticonvulsants, aluminum-containing antacids, and certain cancer treatments
- Chronic disease that affects the kidneys, lungs, stomach, and intestines and alters hormone levels
- Undiagnosed low levels of the sex hormone testosterone
- Lifestyle habits such as smoking, excessive alcohol use, low calcium intake, and inadequate physical exercise

Type II, senile osteoporosis, affects both men and women over the age of 70, although women are twice as likely to develop the disorder.

Juvenile primary osteoporosis is an inherited skeletal disorder. It causes bones to thin in children. Those with the disorder are susceptible to multiple fractures in the arms and legs, especially at the points at which new bone forms.

In some cases, osteoporosis is secondary to another cause. It can accompany endocrine disorders such as acromegaly and Cushing syndrome. It results from excessive use of drugs such as corticosteroids. In those cases, the treatment is directed at curing the principal ailment or at not using the offending drug. Blood or urine tests will diagnose other causes of bone loss or bone density.

Genetic profile

Osteoporosis results from a complex interaction between genetic and environmental factors throughout life. Evidence suggests that peak bone mass is inherited, but current genetic markers are only able to explain a small proportion of the variation in individual bone mass or fracture risk. As of 2021, no specific mode of inheritance had been identified. Heritability of bone mass has been estimated to account for 60% to 90% of its variance. Studies have shown reduced bone mass in daughters of osteoporotic women when compared with controls, in men and women who have first-degree relatives with osteoporosis, and in perimenopausal women who have a family history of hip fracture. Body weight in infancy may be a determinant of adult bone mineral area.

Some scientists believe that environmental influences during early life interact with the genome to establish the functional level of a variety of metabolic processes involved in skeletal growth.

Many candidate genes exist for osteoporosis, but relatively few have been studied. The first candidate gene to be identified was the vitamin D receptor (*VDR*) gene, and

studies are ongoing as to how much this gene accounts for variance in bone mass. The response of bone mass to dietary supplementation with vitamin D and calcium is known to be dependent, in part, on *VDR* polymorphisms. A meta-analysis reported in 2020 that the *VDR BsmI* genotype is associated with increased risk of osteoporosis in Caucasians but not in Asians.

Other genes may aid in establishing who would benefit from treatments like hormone replacement therapy, bisphosphonates, or exercise. Associations between bone mass and polymorphisms have also been found in the estrogen receptor gene, the interleukin-6 genes, the transforming growth factor beta, and a binding site of the collagen type I alpha1 (*COL1A1*) gene.

Recently, T-Plastin (Plastin 3) (Xq23), an actin-bundling protein, has been implicated in X-linked osteoporosis with fractures. Further study in 2021 emphasized the role of plastin 2 with calcium ions in contributing to osteoporosis.

The risk of osteoporosis is greatly determined by peak bone mass, and any gene linked to fractures in the elderly might be associated with low bone mass in

Comparison of healthy dorsal vertebra (left) and one affected by osteoporosis (right). (BSIP/Science Source)

Illustration of a healthy bone (left) and one affected by osteoporosis. (Designua/Shutterstock)

children as well. Genetic studies continue to provide insights into shared genetic mechanisms between bone density mass and both osteoarthritis and osteoporosis.

Environmental influences such as diet, climate, and physical exercise may have significant impact on gene expression as well. In particular, malnutrition early in life is likely to have permanent effects resulting in lowered bone mass.

Juvenile primary osteoporosis is inherited in an autosomal dominant pattern. It is associated with mutations in the *LRP5* gene, which provides protein-making instructions that affect how cells develop, and in regulation of bone mineral density.

Demographics

Significant risk has been reported in people of all ethnic backgrounds. Asian and white women are at greatest risk of bone thinning, because they generally have the lowest bone density. Although the risk is smaller, African-American and Hispanic American women should

also take precaution. An estimated 10% of African-American women over age 50 have osteoporosis, and an additional 30% have low bone density that puts them at risk of developing osteoporosis.

Women in general have four times the risk of developing osteoporosis than men do, and 80% of those affected by osteoporosis are women. In the United States, an estimated eight million American women and two million men have osteoporosis.

An osteoporosis-related fracture will occur in one in two women and one in eight men over the age of 50.

Signs and symptoms

Osteoporosis is often called “the silent disease,” because bone loss occurs without symptoms. People might not know that they have osteoporosis until they have a fracture from a minor bump or fall, or a vertebra collapses. Physical signs of osteoporosis include back pain, loss of height over time, stooped posture, and fractures of vertebrae, wrists, or hips. Osteoporosis can be

detected by a bone mineral density test or even a regular x-ray.

Without preventive treatment, women can lose up to 20% of their bone mass in the first five to seven years following menopause, making them more susceptible to osteoporosis.

Over many years, a sequence of spinal compression fractures may cause kyphosis, the bent-over posture known as dowager's or widow's hump. These fractures rarely require surgery, and they can range from causing minor discomfort to severely painful episodes of back-ache. In either case, pain generally subsides gradually over one to two months.

Diagnosis

Since osteoporosis can develop undetected for decades until a fracture occurs, early diagnosis is important.

A bone mineral density test (BMD) is the only way to diagnose osteoporosis and determine risk for future fracture. The painless, noninvasive test measures bone density and helps determine whether medication is needed to help maintain bone mass, prevent further bone loss, and reduce fracture risk.

Several different machines measure bone density. Central machines, such as dual energy x-ray absorptiometry (DXA or DEXA) and quantitative computed tomography (QCT), measure density in the hip, spine, and total body. Peripheral machines, such as radiographic absorptiometry (RA), peripheral dual energy x-ray absorptiometry (pDXA), and peripheral quantitative computed tomography (pQCT), measure density in the finger, wrist, kneecap, shin bone, and heel.

A physician may be able to observe osteoporotic bone in a routine spinal x-ray; however, BMD tests are more accurate and can measure small percentages of lost bone density. In an x-ray, osteoporotic bone appears less dense, and the image is less distinct, suggesting weaker bone.

There are no official guidelines for osteoporosis screening. Some physicians recommend bone density testing at menopause to begin preventive treatment if necessary. The U.S. Preventive Services Task Force (USPTF) began to recommend in 2018 that women age 65 and older and postmenopausal women younger than 65 with increased risk of osteoporosis have bone measurement testing.

Testing is often recommended for post-menopausal women who have suffered a bone fracture after menopause or who have gone through menopause and have at least one risk factor for the disease. The major risk factors

are low body weight, low calcium intake, poor health, and a family history of osteoporosis.

Testing may also be recommended for elderly men with one of the following risk factors: bone fracture, poor health, or low testosterone levels.

Treatment and management

There are a number of options for preventing and treating bone loss.

Therapeutic options

Various therapies have been shown to be effective in preventing bone loss and increasing bone mass. These include the following:

- **Estrogen.** For women with postmenopausal osteoporosis, estrogen replacement therapy helps to halt bone loss and exerts a modest bone-building effect. Stopping estrogen therapy restarts bone loss, so long-term treatment is usually recommended. For women entering menopause, some physicians recommend estrogen replacement therapy to replace the decreasing supply of naturally occurring estrogen in the body and to enable the skeleton to slow its rate of absorption and to retain calcium. Estrogen is considered the best treatment against osteoporosis. Physicians may recommend combination estrogen and progesterone replacement therapy in women who have an intact uterus, in order to reduce endometrial cancer risk. Some studies indicate a relationship between estrogen use and breast cancer, while others indicate no relationship at all; the issue is still to be determined.
- **Raloxifene.** One of a class of drugs called selective estrogen receptor modulators (SERMs) that appear to prevent bone loss, raloxifene (Evista) produces small increases in bone mass. It is approved for the prevention and treatment of osteoporosis. Like estrogens, SERMs produce changes in blood lipids that may protect against heart disease, although the effects are not as potent as that of estrogen. Unlike estrogens, SERMs do not appear to stimulate uterine or breast tissue.
- **Alendronate.** One of a class of medications called bisphosphonates, alendronate (Fosamax) may prevent bone loss, increase bone mass, and reduce the risk of fractures.
- **Risedronate.** Also from the bisphosphonate family, risedronate (Actonel) has been shown to reduce bone loss, increase bone density, and reduce the risk of fractures.
- **Calcitonin.** A hormone that regulates calcium levels in the blood, calcitonin may prevent bone loss. It is approved for treatment of diagnosed osteoporosis.

QUESTIONS TO ASK YOUR DOCTOR

- If osteoporosis is a genetic disorder, is there anything I can do to prevent developing this disease as I grow older?
- What treatments are typically recommended for a person with osteoporosis?
- What is the probability that I will transmit my osteoporosis to my children?
- Are there books, articles, pamphlets, or other material that provide additional information about osteoporosis?

Preventive options

Measures have been identified that improve bone strength over the lifespan. Physicians recommend that all adult men and women, but particularly men and women over the age of 50, take the following measures to prevent osteoporosis:

- Consume at least 1,000 mg calcium. Foods high in calcium include dairy products, leafy green vegetables, beans, nuts, and whole-grain cereals. Supplements may be taken if adequate intake cannot be achieved through diet.
- Consume 400 IU of vitamin D to enhance calcium absorption.
- Participate in regular weight-bearing exercise, such as walking, jogging, tennis, weight-lifting, and cross-county skiing, to strengthen bones.
- Stop smoking.
- Reduce intake of caffeine to no more than three cups per day.
- Limit alcohol to no more than two drinks per day.
- Avoid excessive amounts of dietary fiber, because it binds to calcium and may interfere with absorption.

Making the house a safer place against falls can decrease risk of fracture in people with osteoporosis. Install handrails on the stairs; remove loose throw rugs; keep rooms and hallways well-lit, including the use of night lights; install handrails beside the tub, shower, and toilet; and place nonskid mats in the bathtub and shower and on tile bathroom floors.

If fractures occur, treatment may require casts, braces, physical therapy, and surgery to assist bone healing.

Prognosis

When osteoporosis is untreated, it can cause serious disability. Osteoporosis can be managed with proper medical care and self-care.

Osteoporosis is associated with 40,000 deaths annually, mostly from complications of surgery or immobilization after hip fractures.

Osteosarcoma

Definition

Osteosarcoma, also called osteogenic sarcoma, is the most common type of bone cancer in young children. Osteosarcoma is destructive to bone development and can spread to other parts of the body.

Description

Osteosarcoma is a malignant tumor that arises from bone tissue and is thus called a primary bone cancer. Primary bone cancers are relatively rare overall; approximately 800 new cases of osteosarcoma occur in the United States every year.

Osteosarcoma occurs most frequently during childhood or adolescence with about 60% of the cases of the disease developing during the second decade of life. The incidence of osteosarcoma rises again among people in their 40s and 50s.

False-color CT scan of the knee joints showing osteosarcoma located in the tibia at left of image. The head of the tibia bone (center left) is cancerous (green). (GCa/Science Source)

Osteosarcoma may occur in any bone but develops most commonly in long bones, particularly near the knee or in the upper arm. The cancer starts growing within the bone and forms an expanding, ball-like mass called a tumor. The tumor eventually breaks through the surface of the bone and begins to invade adjoining structures, such as muscles. If untreated, the disease usually appears elsewhere in the same limb and metastasizes to distant parts of the body, such as the lungs.

Genetic profile

Some cases of osteosarcoma are likely to have a genetic basis, as numerous genetic abnormalities have been found in patients with osteosarcoma. Osteosarcoma is also the most common second cancer to develop in survivors of the genetic cancer retinoblastoma, suggesting that osteosarcoma may also have genetic contributions.

Other cancers are often associated with osteosarcoma. These are considered cancer syndromes, as the occurrence of more than one type of cancer is part of the syndrome's phenotype. The occurrence of osteosarcoma can be linked to a treatment for the primary disease, or it can be a result of a genetic predisposition, as is the case with Li-Fraumeni syndrome and retinoblastoma.

Li-Fraumeni syndrome (LFS) is an autosomal dominant disorder caused by a mutation in the *TP53* gene. Frederick Li and Joseph Fraumeni first described it in 1969 based on clinical phenotypes associated with other cancers. Germline mutations in the *TP53* gene have been identified among family members with LFS. *TP53* is a gene that functions in the regulation of the cell cycle, and mutations occur in 50% and 70% of cancer and LFP cases, respectively. Among those affected with LFS, osteosarcoma is the most common bone cancer to be associated with other symptoms of the syndrome.

Hereditary retinoblastoma is a rare, autosomal dominant disease that causes malignant eye tumors in children. It is caused by mutations in the *RBI* gene, which acts as a tumor suppressor by inhibiting proteins that are involved in cell replication. Individuals who have retinoblastoma often have increased risk of developing other cancers later on in life, including osteosarcoma. Heritable mutations of *RBI* occur in germ cells, but spontaneous mutations of *RBI* can also occur in somatic cells. These types of mutations in *RBI* are found in 30%–70% of osteosarcoma patients. It is thought that this may be because *RBI* is important in the inhibition of proteins that cause unregulated osteoblast proliferation or stimulate cell differentiation.

Demographics

Of the 800 new cases of osteosarcoma that are diagnosed in the United States each year, approximately 400

are in children and teens. Teens are most at risk for osteosarcoma, and it occurs more often in males than in females. It also appears that African Americans have a slightly higher risk than Caucasians.

Signs and symptoms

There are numerous theories regarding the causes of osteosarcoma. Many cases occur during a time of rapid bone growth, which is why it is often seen in teenagers. Individuals with Paget's disease are also more susceptible to osteosarcoma because of the associated constant breaking down and remodeling of their bones. This suggests that the cancer may develop when the body loses its ability to control the multiplication of certain bone cells. Other cases arise in people who have been exposed to radiation, either accidentally or as part of a medical treatment.

Common early symptoms of osteosarcoma are often hard to diagnose. There may be pain or swelling at the site of the tumor, but these symptoms may not initially seem serious in a young, active person. Thus, the patient or medical personnel may attribute the symptoms to growing pains or an injury from physical activity, and the diagnosis may be delayed. Eventually, it is usually possible to feel a firm lump on the bone and this lump will be sensitive to the touch.

Diagnosis

The complete diagnosis of osteosarcoma is a complicated process that requires a variety of tests and the help of several medical specialists. Physicians must first determine the stage of the cancer (the extent to which it has spread) and the grade of the cancer (the degree of cancerous qualities shown by cells in a biopsy specimen). A higher grade or stage indicates a more serious disease than a lower grade or stage.

Initial diagnosis begins with x-ray images of the affected area. These pictures will show a cancerous growth within the bone, which is often described as having a "moth-eaten appearance." The patient then needs further tests such as computed tomography (CT, CAT) or magnetic resonance (MR, MRI) imaging scans of the tumor, a chest x-ray series or chest CT, and a nuclear medicine scan of the entire skeleton (bone scan). This imaging will determine the parts of the body that are affected by the cancer and to what extent the cancer has spread from the initial areas. Blood tests, such as measurements of alkaline phosphatase (ALP), provide additional information. It is unclear why ALP levels are increased in cases of osteosarcoma, but it remains a diagnostic tool for determining the stage of the cancer.

KEY TERMS

Alkaline phosphatase (ALP)—An enzyme that is found in the blood and that helps to break down proteins in the body. ALP can be present in different forms depending on where it was synthesized. ALP can be made in the liver, kidneys, intestines, and bones.

Chemotherapy—Treatment of cancer with synthetic drugs that destroy the tumor either by inhibiting the growth of the cancerous cells or by killing the cancer cells.

Grade—As a noun: a classification of the cancerous qualities of an individual tumor. A higher grade indicates a more serious disease than does a lower grade. As a verb: to classify the cancerous qualities of an individual tumor.

Malignant—Cancerous.

Metastasize—To spread to another part of the body.

Monoclonal antibody (mAB)—A protein, produced in large quantities in a laboratory, designed to attack a specific target in the body.

Osteogenic—Derived from or containing bone cells.

Osteogenic sarcoma—A form of cancer that originates in the bone.

Paget's disease—A non-cancerous disease marked by excessive growth of abnormal bone material.

Retinoblastoma—A cancerous tumor of the eye.

Stage—As a noun: the extent to which an individual cancer has spread. A higher stage indicates a more serious disease than does a lower stage. As a verb: to determine the extent to which an individual cancer has spread.

Tumor—An abnormal growth of cells. Tumors may be benign (non-cancerous) or malignant (cancerous).

Finally, physicians require a biopsy sample of the diseased bone, obtained with a needle or by a surgical procedure, to be sure that the disease is truly cancer and to identify its grade. There are numerous tests, mostly involving examinations under the microscope, to perform on this biopsy specimen.

Treatment and management

Before the 1980s, limb amputation was the standard treatment for osteosarcoma. Usually, however, the tumor had already spread elsewhere in the body and the patient eventually died of the disease.

QUESTIONS TO ASK YOUR DOCTOR

- What type of osteosarcoma do I (or my family member) have? How does this affect treatment options?
- What stage is the cancer at and has it spread to other organs?
- When will treatment begin and how long will it last? What common side effects can I expect?
- Are there genetic or fertility decisions I should consider?
- Based on the treatment plan, what are the chances the cancer will come back?

Newer medical developments make it possible to avoid amputation and treat many patients with osteosarcoma successfully. Patients almost always receive chemotherapy with more than one drug (multi-drug therapy) before surgery to shrink the original tumors and reduce the likelihood of the cancer spreading to other areas of the body. Techniques known as limb-sparing surgery often allow removal of the tumor while saving the rest of the extremity. Afterward, patients usually continue to receive chemotherapy and may require bone grafts or prosthetic devices to replace parts of bones or joints that have been removed as part of their treatment.

Future treatments under investigation include the development of monoclonal antibodies that destroy specific cancer cells, techniques to slow cancer growth by controlling certain genes involved in cell growth or replication, and bone-specific chemicals that directly target areas of active bone growth and slow it down.

Alternative and complementary therapies

Current treatments with chemotherapy and surgery offer a substantial improvement over past therapies. While radiation therapy is often not as successful as chemotherapy in treating osteosarcoma generally, it can sometimes be helpful in keeping tumor growth under control before other treatments can be put into place.

Alternative therapies often include clinical trials that are testing new medications or technologies, but these are normally only provided when a patient's cancer is not responding to traditional forms of treatment.

Complementary methods of therapy are not considered curative but can often be helpful in minimizing pain or suffering caused by traditional treatment. These

methods can focus on stress relief through talk or art therapy, or use of acupuncture to treat pain or nausea.

Prevention of osteosarcoma is difficult since doctors do not know the cause of most cases. Until research can provide information and tools that make prevention possible, early detection of the disease remains vital. Anyone with persistent pain in a bone or limb should report this to a physician. People with special risk factors including Paget's disease, exposure to significant amounts of radiation, or a family history of certain types of cancer must be especially vigilant.

Prognosis

Early detection is extremely important. Prognosis for an individual patient reflects a complex balance among the extent to which the cancer has already spread at the time of diagnosis, the aggressiveness of the cancer, and the response to chemotherapy. The best chance of a cure occurs when a tumor shows no sign of metastasis at the time of original surgery, is well confined within a single bone, responds well to chemotherapy, and can be completely removed. The five-year survival rate for osteosarcoma in a long bone of a limb is about 70%. A physician must follow all patients closely to watch for cancer recurrence.

Otopalatodigital syndrome

Definition

Otopalatodigital (OPD) syndrome, also called digi-tootopalatal syndrome or palatootodigital syndrome, is a rare X-linked genetic disorder that affects bone and facial structure. OPD is fully expressed in males. Females are only mildly affected.

Description

There are two forms of OPD syndrome. Type I is inherited through an X-linked trait with intermediate expression in females, while type II is inherited through an X-linked recessive trait. OPD syndrome type I is also called Taybi syndrome. OPD syndrome type II is alternatively called Andre syndrome, cranioorodigital syndrome, or faciopalatoosseous (FPO) syndrome.

A genetic disorder called frontometaphyseal dysplasia, or FMD, has very similar features to type I OPD syndrome.

There are three recognized forms of a genetic disorder called Larsen syndrome: an autosomal dominant type, a recessive type, and a lethal type. All three of these syndromes have similar symptoms to those seen in individuals affected with OPD syndrome. Some research has suggested that Larsen syndrome, recessive type, may in fact be type II OPD syndrome.

As the various names of OPD syndrome suggest, this disorder is characterized by malformations and/or dysfunctions of the ears (-oto-), palate (-palato-), fingers and toes (-digito-), skull (-cranio-), mouth (-oro-), face (-facio-), and bones (-osseo-). Some of the characteristics common to both types of OPD syndrome include: a cleft palate, a prominent forehead, a broad nose, widely spaced eyes (hypertelorism), a downward slanting of the opening between the upper and lower eyelids (palpebral fissures), conductive hearing loss, short fingers and toes (brachydactyly), an abnormal inward curving of the fingers (clinodactyly), a caved in chest at birth (pectus excavatum), short stature (dwarfism), and a congenital dislocation of the elbows caused by a misalignment of the head of the large bone in the forearm (radius).

Genetic profile

Both forms of OPD syndrome are X-linked. The gene mutation responsible for the appearance of type I OPD syndrome has been tentatively assigned to the Xq28 band. It is also believed that type II OPD syndrome is an allelic variant of type I OPD, which is to say that each form of OPD syndrome is caused by different mutations in the same gene or in overlapping genes at the same

KEY TERMS

Brachydactyly—Abnormal shortness of the fingers and toes.

Cleft palate—A congenital malformation in which there is an abnormal opening in the roof of the mouth that allows the nasal passages and the mouth to be improperly connected.

Clinodactyly—An abnormal inward curving of the fingers or toes.

Conductive hearing loss—Hearing loss that is the result of a dysfunction of the parts of the ear responsible for collecting sound. In this type of hearing loss, the auditory nerve is generally not damaged.

Hypertelorism—A wider-than-normal space between the eyes.

Hypospadias—An abnormality of the penis in which the urethral opening is located on the underside of the penis rather than at its tip.

Omphalocele—A birth defect where the bowel and sometimes the liver protrudes through an opening in the baby's abdomen near the umbilical cord.

Palpebral fissures—The opening between the upper and lower eyelids.

Pectus excavatum—An abnormality of the chest in which the sternum (breastbone) sinks inward; sometimes called "funnel chest."

chromosomal location. Recessive type Larsen syndrome is also believed to be either another allelic variant of OPD syndrome, or identical to type II OPD syndrome. Another extremely rare genetic disorder, Melnick-Needles syndrome, also has an overlapping of symptoms with type II OPD syndrome. It is felt that this syndrome is also possibly an allelic variant of OPD syndrome.

OPD syndrome is transmitted via the X chromosome. A female generally possesses two X chromosomes, one from her mother and one from her father. A male generally possesses only a single X chromosome, that from his mother. He gets a Y chromosome from his father. Certain rare exceptions to these inheritance patterns are seen, but in general, a female is an XX and a male is an XY. It is for this reason that X-linked disorders are generally seen in greater numbers of males than females. The male does not possess a second X chromosome that can be expressed. A male either has a mutation on his X chromosome, or he does not. A female, on the other hand, can be either homozygous or heterozygous

for an X-linked trait. That is, she can either have two identical copies of this trait (homozygous) or only one copy of this trait (heterozygous).

Type I OPD syndrome is transmitted through a dominant trait. A child of a type I OPD syndrome affected parent has a 50% chance of also being affected with type I OPD syndrome.

Type II OPD syndrome is transmitted through an X-linked recessive trait. A child of a type II OPD syndrome affected parent has a 50% chance of also inheriting the gene for the type II OPD syndrome. Subsequently, if that child is male, he will have expression of the disorder. If it is a female child, then she generally will have milder features. Girls who are homozygous for type II OPD syndrome (inheriting the gene from each parent) will exhibit more severe symptoms than girls who are heterozygous for type II OPD syndrome. Males affected with type II OPD syndrome exhibit symptoms similar to those seen in homozygous girls.

Demographics

The incidence of occurrence of OPD syndrome types I and II in 2015 were each fewer than 1 in 100,000 people. However, type I OPD syndrome is more common than type II OPD syndrome and more than 100 cases had been reported in the medical literature. In 2015, only 40 detailed cases of type II OPD syndrome had been described in the medical literature.

Signs and symptoms

The severity of symptoms experienced by those people affected with OPD syndrome varies widely from practically asymptomatic to symptoms so severe that they cause infantile or prenatal death. In type II OPD syndrome, males are generally affected with far more severe symptoms than females.

There are six abnormalities of the face and head that characterize OPD syndrome: a cleft palate, downwardly slanting openings between the eyelids, widely spaced eyes (hypertelorism), a prominent forehead, a broad nose, and conductive hearing loss.

Conductive hearing loss results from a blockage of the auditory canal or some other dysfunction of the eardrum or one of the three small bones within the ear (the stapes, the malleus, and the incus) that are responsible for collecting sound. In this type of hearing loss, the auditory nerve is normal. In individuals affected with OPD syndrome, complete deafness from birth is often observed. In those individuals with partial hearing, speech disabilities related to this hearing loss are quite common.

QUESTIONS TO ASK YOUR DOCTOR

- How does the genetic basis of the two types of otopalatodigital syndrome differ from each other?
- What signs and symptoms are characteristic of this disorder?
- What kinds of treatment are available for otopalatodigital syndrome, and at what stage of a child's life should each treatment be used?
- Can you recommend any websites that have additional information about this disorder?

In addition to the abnormalities of the head, universal characteristics of OPD syndrome affected individuals also include: abnormally short fingers and toes (brachydactyly); abnormal inward curving of some fingers (clinodactyly); short nails; a congenital dislocation of the elbows, and sometimes the knees; a caved in chest (pectus excavatum) at birth; and growth retardation.

Symptoms that are characteristic of type I OPD syndrome include curvature of the spine (scoliosis); generalized bone malformation, particularly in the bones of the limbs and ribcage; broad distal digits, malformed or missing teeth (hypodontia); and mild intellectual disability.

Symptoms that are characteristic of type II OPD syndrome include: low-set ears, flattened vertebrae in the spine, bowing of the bones of the limbs, flexed overlapping digits, a malformation or complete absence of the large bone in the shin (fibula), malformations of the hips, a small opening in the abdominal wall (hernia) at the navel (omphalocele), and a malformation of the male genitalia in which the opening of the urethra is located on the underside of the penis, rather than at the tip of the penis (hypospadias).

Diagnosis

A diagnosis of OPD syndrome is suggested when a patient presents the five characteristic abnormalities of the head and face accompanied by conductive hearing loss. This diagnosis is confirmed by the observance of brachydactyly and congenital dislocation of the elbows and/or knees.

Type I OPD syndrome is differentially diagnosed from type II OPD syndrome by the appearance of scoliosis. Type II OPD syndrome is differentially diagnosed from type I OPD by the presence of an omphalocele and greater malformations of the bones of the ribcage.

Treatment and management

There are currently no treatments aimed specifically at OPD syndrome. Instead, treatment is on a case-by-case and symptom-by-symptom basis.

Malformations of the head and face can generally be corrected, if necessary, by surgeries. In certain instances, the conductive hearing loss experienced by individuals with OPD syndrome may also be corrected through surgery. When it cannot, hearing aids may be required.

Many of the skeletal abnormalities seen in OPD syndrome affected individuals can either be corrected by surgery or can be alleviated through the use of braces until the bones become more fully developed.

Malformations of the male genitalia and the omphalocele observed in type II OPD syndrome affected infants can also be corrected by surgery.

Certain OPD affected individuals may also benefit from treatments with growth hormone.

In cases of mild intellectual disability or speech problems, early intervention programs for these types of developmental delays may also be of benefit.

Prognosis

Most individuals affected with type I OPD syndrome can expect to lead full lives if medical treatments, including corrective surgeries, are sought. Many individuals affected with type II OPD syndrome die either prior to birth or as infants due to respiratory failure associated with the malformation of the bones of the ribcage. If these individuals survive infancy, they also may expect to live full lives after corrective surgeries and other medical treatments.

Paul A. Johnson

Ovarian cancer

Definition

Ovarian cancer is a disease in which the cells in the ovaries become abnormal and start to grow uncontrollably, forming tumors. Ninety percent of all ovarian cancers develop in the cells that line the surface of the ovaries and are called "epithelial cell tumors." Despite advances in treatment, ovarian cancer remains one of the most lethal cancers.

Description

The ovaries are a pair of almond-shaped organs that lie in the pelvis on either side of the uterus. The fallopian tubes connect the ovaries to the uterus. The ovaries produce and release an egg each month during a woman's menstrual cycle. In addition, they produce the female hormones estrogen and progesterone, which regulate and maintain the proper growth and development of female sexual characteristics.

Ovarian cancer is the fifth most common cancer among women in the United States. It accounts for 4% of all cancers in women but is very difficult to discover in the early stages, often because there are no obvious warning signs, and the disease can progress relatively quickly. In addition, the ovaries are situated deep in the abdomen, and small tumors might not be detected easily during a routine

Enlarged uterus removed from a 60 year old woman with ovarian cancer and uterine fibroids. Fibroids are benign (non-cancerous) tumors of fibrous and muscular tissue. (Dr P. Marazzi/Science Source)

physical examination. The death rate due to ovarian cancer is higher than that of any other cancer among women, since it often is detected at advanced stages.

Ovarian cancer can develop at any age, but more than half the diagnoses are among women who are 63 years or older. It is more common in white women than in African American women. The vast majority of women with ovarian cancer have no family history of the disease, but for about 5% to 10% of individuals there may be a very strong family history of ovarian cancer or other cancers such as breast cancer. In those cases, a specific genetic alteration may run in the family, causing a predisposition to ovarian cancer and other associated cancers.

Genetic profile

Cells in ovarian tissue normally divide and grow according to controls and instructions by various genes. If these genes have changes (mutations) within them, the instructions for cellular growth and division may be altered, causing abnormal or uncontrolled cell growth that can lead to ovarian cancer. In this way, all ovarian cancers are genetic, because they all result from changes within genes.

The difference is that most ovarian cancers are caused by sporadic changes within the genes, and only a minority are caused by inherited genetic alterations. Most ovarian cancers occur later in life after years of exposure to various environmental factors (e.g., asbestos exposure, or smoking) that can cause sporadic genetic alterations.

A small proportion of ovarian cancer is caused by inherited genetic mutations. In 1994, a breast and ovarian cancer susceptibility gene, known as *BRCA1* (location 17q21), was identified, and the discovery of *BRCA2* (location 13q12) followed shortly in 1995. Women with mutations in these genes have an increased risk for breast and ovarian cancer, and men have an increased risk for prostate cancer. Men with a *BRCA2* mutation also have an increased risk for breast cancer. Slightly increased risks for colon and pancreatic cancers in men and women are also associated with *BRCA2* mutations.

BRCA1 and *BRCA2* mutations are inherited in an autosomal dominant manner. People who have one copy of a *BRCA* alteration have a 50% chance of passing it on to each of their children, regardless of that child's gender. Nearly all individuals with mutated *BRCA* have a family

history of the mutation, usually a parent with it. In turn, they also may have a very strong family history of breast, ovarian, prostate, colon, and/or pancreatic cancers. Aside from *BRCA1* and *BRCA2*, there likely are other cancer susceptibility genes that are still unknown.

In addition to *BRCA1* and *BRCA2*, ovarian cancer may be present in rare genetic cancer syndromes. In those instances, an individual may have other health problems that are unrelated to cancer as well as a family history of a wide variety of cancers and symptoms. For example, hereditary non-polyposis colorectal cancer (HNPCC) is a syndrome that often involves cancers of the colon, uterus, ovaries, and stomach. HNPCC is due to changes in several genes, including *hMLH1*, *hMSH2*, *hMSH6*, and *hPMS2*. These genes are unrelated to *BRCA1* and *BRCA2* but are still correlated to the development of ovarian cancer.

Demographics

On average, a North American woman faces a lifetime risk of about one in 78 of developing ovarian cancer. The American Cancer Society (ACS) states that in 2021, about 21,410 new cases of ovarian cancer will be diagnosed in the United States and that 13,770 women will die from the disease. The ACS notes that the rate at which women are diagnosed with ovarian cancer has been slowly declining since 2000. Specific *BRCA* mutations are common in certain ethnic groups, which may make hereditary ovarian cancer more common in these populations. Certain *BRCA* mutations are more common in the

Ashkenazi (Eastern European) Jewish, Icelandic, Dutch, French Canadian, and West African populations.

Signs and symptoms

Ovarian cancer has no specific signs or symptoms in the early stages of the disease; however, some symptoms are commonly associated with it:

- Pain or swelling in the abdominal area
- Bloating and general feeling of abdominal discomfort
- Constipation, nausea, or vomiting
- Loss of appetite, fatigue
- Unexplained weight gain (generally due to fluid buildup from the cancer in the abdomen)
- Vaginal bleeding in women who have already gone through menopause

Only a physician can assess whether symptoms are an indication of early ovarian cancer, and it is important to seek medical care immediately if any of the above-mentioned symptoms is present.

A family history of ovarian cancer puts a woman at an increased risk for developing the disease. In addition, if a woman has had, or has a family history of, breast cancer then she may be at an increased risk for ovarian cancer. Signs of possible mutations in *BRCA1* or *BRCA2* in a family signify hereditary breast or ovarian cancer and can include:

- Several relatives with cancer
- A larger number of relatives with cancer than unaffected relatives
- Close genetic relationships between people with cancer, such as parent-child, sibling-sibling
- Onset of cancer before the ages 45 to 50
- An individual with both breast and ovarian cancer
- An individual with bilateral or multi-focal breast cancer
- The presence of ovarian, prostate, colon, or pancreatic cancers in the same family
- Case(s) of breast cancer in men

BRCA mutations may be suspected if someone has the above features in his or her family, and he or she is of a particular ethnic group particularly at risk. This is because specific *BRCA1* and *BRCA2* mutations are known to be more common in some groups.

Diagnosis

If a woman has symptoms of ovarian cancer, a pelvic examination is conducted to feel the ovaries to determine whether they have enlarged, which is indicative of a tumor. Blood tests to determine the level of the protein carbohydrate antigen 125 (CA-125) may be done as well.

Ovarian cancer. (Shutterstock/kanvictory)

CA-125 blood levels may be high when a woman has ovarian cancer. Pelvic or transvaginal ultrasound also may be used to get several views of the ovaries and to carefully check their shapes and structures. A CT scan may be helpful if the ultrasound is technically unsatisfactory for accurate interpretation.

Biopsy and surgery are necessary in order to determine the type of tumor, as not all tumors are cancerous. If the tumor appears to be small, a procedure known as laparoscopy may be used to further investigate and make a diagnosis. A tiny incision is made in the abdomen, and a slender, hollow, lighted instrument is inserted to enable the doctor to view the ovary more closely and to obtain a biopsy. If the ovary has suspicious findings on laparoscopy and biopsy, a laparotomy to remove that ovary is usually performed. Large masses are normally investigated by open surgery.

Standard imaging techniques such as computed tomography (CT) and magnetic resonance imaging (MRI) could be used to determine whether the disease has metastasized (spread to other parts of the body).

There is DNA-based genetic testing to identify a *BRCA1* or *BRCA2* mutation in an individual. A blood sample is used, and both *BRCA* genes are studied for abnormalities in their sequences. There is also targeted testing for people in high-risk ethnic groups where the *BRCA* mutations common to that group can be tested for specifically.

Women without cancer who test positive for a *BRCA* alteration are at a significantly increased risk to develop the associated cancers. A woman's risks associated with a mutant *BRCA1* are 40% to 60% for ovarian cancer by age 70 and 55% to 65% for breast cancer by age 70. A woman's risks with a *BRCA2* alteration are 16% to 27% for ovarian cancer by age 70 and approximately 45% for breast cancer by age 70.

Women with ovarian cancer who are found to have a *BRCA* mutation are at an increased risk to develop breast cancer. For some women, this may be a new risk that they were not aware of before the testing, particularly if they have no family history of breast cancer.

Women with a *BRCA2* mutation may be at slightly increased risk for colon and pancreatic cancers. Additionally, because the testing process and test results are quite complex, everyone should receive proper genetic counseling before pursuing any *BRCA1* and *BRCA2* testing. Prenatal *BRCA* testing is available but is rarely performed unless accompanied by extensive genetic and psychological counseling.

Treatment and management

As with many other cancers, treatment is determined by the exact size, type, and stage of ovarian cancer, and it

This CT scan of the pelvis shows a large multi-lobulated cystic mass (green), which is ovarian cancer. (Matthew Bologna/Medical Body Scans/Science Source)

is often unique to an individual. However, the cornerstone of treatment for ovarian cancer is debulking surgery, which removes as much of the cancer as is feasible. This may require a laparoscopic or open surgical procedure in order to remove as much cancerous tissue as possible. Other organs, such as the uterus and fallopian tubes, may also be removed, especially if the cancer has spread. Chemotherapy following surgery is used to destroy any remaining cancer cells. Hormone therapy may be used to suppress tumor growth of refractory stromal tumors rather than the more common epithelial cell tumors. Immunotherapy is used to enhance the activity of the immune system. Radiation therapy is not typically used for ovarian cancer, because it is not as effective as other treatments.

New Treatments

In 2021, promising research was underway to develop treatments that stop tumor growth in treatment-resistant cancer cells and kill cancer stem cells, which are cancer cells that act like stem cells. These cells self-renew, enabling tumor initiation, and they differentiate into rapidly proliferating non-stem cells that can accelerate tumor growth.

Preventing and Predicting Recurrence

Ovarian cancer has a high relapse rate: between 70% and 80% of patients who achieve remission will have a recurrence of disease. When it recurs, it often comes back within the first two years following treatment, sometimes as early as six months after treatment ends. Because recurrence risk is so high, researchers are focusing on identifying precision assays, which are biomarkers to detect the disease earlier, predict recurrence, and guide

Illustration of ovarian cancer. (Alila Medical Media/Shutterstock)

treatment decision-making. In 2021, a clinical trial was launched to evaluate whether coffee products made using the leaves of the *Artemisia annua* plant can prevent ovarian cancer recurrence. The same year, Mijin Kim, PhD, a postdoctoral fellow in molecular pharmacology at Memorial Sloan Kettering Cancer Center in New York earned Marie-José Kravis Women in Science Endeavor fellowship grant for her work on a new sensor technology designed for early detection of ovarian cancer. The technology consists of carbon nanotubes that are able to detect and distinguish subtle differences in physiochemical properties of ovarian cancer biomarkers.

Screening

In 2021, the results of a British trial that followed more than 200,000 women ages 50 to 74 over the course of 16 years found that annual population screening for ovarian cancer detected cancers earlier, rather than in the later stages of the disease, but did not reduce deaths attributable to this aggressive disease. The investigators concluded that screening was not effective in women with no symptoms of ovarian cancer, but they asserted that for women who do have symptoms, and for those at high risk for ovarian cancer, screening and early detection can make a difference in terms of their quality of life. Screening recommendations for women at high risk of developing ovarian cancer may include:

- Pelvic examination every six months or yearly, starting at age 25 to 35

KEY TERMS

Alteration—Change or mutation in a gene, specifically in the DNA that codes for the gene.

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes.

Computed tomography (CT) scan—An imaging procedure that produces a three-dimensional picture of organs or structures inside the body, such as the brain.

Laparoscopy—A diagnostic procedure in which a small incision is made in the abdomen, and a slender, hollow, lighted instrument is passed through it. The doctor can view the ovaries more closely through the laparoscope and, if necessary, obtain tissue samples for biopsy.

Laparotomy—An operation in which the abdominal cavity is opened up.

Magnetic resonance imaging (MRI)—A technique that employs magnetic fields and radio waves to create detailed images of internal body structures and organs, including the brain.

Pelvic examination—A physical examination performed by a physician, often associated with a Pap smear. The physician inserts a finger into a woman's vagina, attempting to feel the ovaries directly.

Transvaginal ultrasound—A probe is inserted into the vagina, and the ovaries are visualized using sound waves. Color Doppler imaging measures the amount of blood flow, as tumors sometimes have high levels of blood flow.

- Transvaginal ultrasound with color Doppler imaging every six months or yearly, beginning at age 25 to 35
- Yearly blood CA-125 testing, starting at age 25 to 35

Women with a *BRCA1* or *BRCA2* gene mutation are also at an increased risk for breast cancer. Screening recommendations for them may include:

- Monthly breast self-examination
- Examination of their breasts by a physician or nurse every six months or yearly, starting at age 25 to 35
- Mammograms (imaging of the breasts) yearly, starting at age 25 to 35

Specific screening programs may vary by physician. In addition to cancer screening, women with *BRCA1* or *BRCA2* gene mutations should know about preventive surgery options. They may consider having their healthy ovaries and/or breasts removed in order to reduce their risks

QUESTIONS TO ASK YOUR DOCTOR

- Ovarian cancer is common among the women in my family; what tests should I have to monitor my risk for the disease?
- What information is used to make a diagnosis of ovarian cancer?
- What determines the different stages of ovarian cancer?
- Which types of treatment are recommended for my ovarian cancer, and what side effects should I expect as a result of these treatments?

of developing ovarian and/or breast cancer in the future. Women may be more agreeable about having their ovaries removed, because ovarian cancer is difficult to detect; however, this surgery ends their ability to have children and automatically triggers the start of menopause. Both preventive surgeries greatly reduce a woman's cancer risk, but they can never eliminate it entirely.

For people with cancer or at high risk for it, support, education, and discussion groups are available.

Prognosis

Because ovarian cancer is not usually diagnosed until it is in an advanced stage, it is the most terminal of all the female cancers of the reproductive organs. As of 2021, it was estimated that only 48% of women diagnosed with ovarian cancer would survive past five years. When ovarian cancer is diagnosed before it has spread to other organs, about 93% of the patients will survive five years or more. Unfortunately, fewer than 20% of all cancers are found at this early stage.

There appears to be no difference in the survival rates of women who develop ovarian cancer because of *BRCA* mutations and those whose ovarian cancer is caused by another factor. Because unaffected people in a family with a *BRCA* mutation may be in high-risk screening programs, the hope is that they may be able to have any of their cancers detected earlier, which could give a better prognosis.

Pallister-Hall syndrome

Definition

Pallister-Hall syndrome (PHS) is an extremely rare developmental disorder characterized by a spectrum of features ranging from mild (extra fingers or toes or a non-cancerous malformation in the hypothalamus region of the brain) to severe (laryngotracheal cleft, an opening between the windpipe and voice box that can cause death in newborns).

Description

First reported in 1980 by American geneticist Judith G. Hall and American medical doctor Philip D. Pallister, PHS is often diagnosed at birth. Some symptoms are immediately noticeable, including short limbs, extra digits, unusual facial features, or blockage of the anal opening. Some signs, such as intellectual disability and abnormalities of the heart, lung, or kidneys, must be diagnosed by a physician.

Newborn infants with PHS must be carefully monitored for signs of hypopituitarism (insufficient production of growth hormones by the pituitary gland), which can cause fatal complications if not promptly treated. Similarly, inadequate activity of the adrenal gland can be lethal in newborns. If not immediately recognized, an imperfectly formed anus can also develop serious complications in a newborn. PHS is sometimes inappropriately considered part of the CAVE (cerebro-acro-visceral early lethality) group of disorders.

Genetic profile

PHS has an autosomal dominant inheritance, meaning that it can occur in either sex and is passed from generation to generation when an abnormal gene is received from one parent and a normal gene is received from the other. Roughly 25% of diagnosed patients have a *de novo* mutation. Affected patients have a 50% chance

of passing the disorder to each offspring. In most such cases, signs and symptoms in affected offspring are similar to those of the parents. However, PHS is more commonly found in isolated cases involving individuals with no family history of the disorder. Truncating mutations in the middle portion of the *GLI3* gene affects zinc finger transcription factor leading to PHS (chromosomal locus 7p13). This gene provides instructions for making a protein that controls gene expression, the process that regulates whether genes are turned on or off in particular cells known as the sonic hedgehog signaling pathway. The *GLI3* mutations typically lead to the production of an abnormally short version of the GLI3 protein.

Demographics

Only about 100 cases of this very rare genetic disorder have been diagnosed worldwide. Males seem to be more affected than females. The disorder is not limited to particular ethnic groups. Some researchers have proposed that many patients with Pallister-Hall signs and symptoms have been misdiagnosed as having a related genetic disorder, isolated post-axial polydactyly type A (PAP-A).

Signs and symptoms

This disorder is noted for a wide range of signs and symptoms, including the following:

- Abnormalities of the head, neck, and facial areas including short neck, short midface, flat nasal bridge, small tongue, noticeable underdevelopment of one jaw compared to the other, asymmetric skull, cleft palate and other irregularities of the palate, cleft larynx or epiglottis, cysts on the gums, and ears that are small, low-set, and abnormally rotated toward the back of the head
- Hypothalamic hamartoblastoma, a noncancerous tumor in the hypothalamus. It grows at the same rate as nearby brain tissue, up to 4 cm across, taking the place of the hypothalamus. Most hypothalamic hamartomas have no symptoms, but in some cases they can cause

KEY TERMS

Adrenal gland—A triangle-shaped endocrine gland, located above each kidney, that synthesizes aldosterone, cortisol, and testosterone from cholesterol. The adrenal glands are responsible for salt and water levels in the body, as well as for protein, fat, and carbohydrate metabolism.

Hypothalamus—A part of the forebrain that controls heartbeat, thirst, hunger, body temperature and pressure, blood sugar levels, and other functions.

Pituitary gland—A small gland at the base of the brain that is responsible for releasing many hormones, including luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

neurological problems including gelastic epilepsy, which causes chest and diaphragm movements similar to those that occur during laughter.

- Inhibited flow of cerebrospinal fluid in the brain
- Limb abnormalities including short limbs, extra fingers or toes (central or postaxial polydactyly), webbing of fingers or toes (syndactyly), abnormally small fingernails or toenails, or absent nails
- Respiratory abnormalities including underdeveloped or abnormally developed lungs
- Anus lacking the usual opening
- Congenital heart defects
- Kidneys with abnormal development or placement
- Underdeveloped or abnormally developed adrenal, pituitary, or thyroid glands. This can lead to decreased activity of these glands. Some Pallister-Hall newborns cannot survive due to insufficient activity of the adrenal gland. An underdeveloped pituitary gland can also have lethal consequences. Symptoms of hypopituitarism may include hypoglycemia, jaundice, or unusual drowsiness.
- In males, unusually small penis, underdeveloped testicles, or failure of one or both testes to descend normally
- Retarded growth in most patients
- Mild intellectual disability
- Spinal abnormalities
- Dislocated hips
- Signs of puberty may appear unusually early.

Diagnosis

Both clinical examination and family history are used to diagnose PHS.

The hallmark clinical findings are hypothalamic hamartoma (a noncancerous tumor in the hypothalamus), as well as extra fingers or toes. Another sign useful for diagnostic purposes is bifid epiglottis, a cleft in the thin flap of cartilage behind the base of the tongue. This particular malformation is almost never seen except in cases of PHS. It rarely causes problems.

Prenatal testing may be conducted by ultrasound; however, its effectiveness in detecting PHS is not conclusive.

A molecular genetic test exists to scan the coding regions of the *GLI3* gene for mutations, as this is the only gene known to cause this disorder. The test can differentially diagnose a patient from other causes of polydactyly.

Treatment and management

Management depends on the specific signs and symptoms present.

Unless there are unusual complications, hamartoblastomas are usually left in place. However, it is sometimes necessary to surgically remove a hamartoblastoma when it causes undue pressure on the brain (hydrocephalus). Hamartoblastomas are usually monitored throughout the life of the patient. Typically, magnetic resonance imaging (MRI) is used because hypothalamic hamartomas are sometimes not visible on computerized tomography (CT) scans or cranial ultrasound examinations.

Because of the dangers posed by adrenal insufficiency, Pallister-Hall patients are often assessed for cortisol deficiency. Cortisol (hydrocortisone) is an important steroid hormone released by the adrenal glands. Patients are also likely to see an endocrinologist to evaluate their growth hormone, luteinizing hormone, follicle-stimulating hormone, and thyroid hormone levels. X-rays may be taken of limbs, and the kidneys may be examined by ultrasound. The epiglottis may be examined by laryngoscope, an instrument used to view the larynx through the mouth.

If patients show evidence of aspiration (when breathing forces foreign matter into the lungs) they should be seen immediately by an ear, nose, and throat specialist to determine whether laryngotracheal cleft is present.

Newborns with hypopituitarism should immediately be given hormone replacement therapy and watched closely for life-threatening complications.

A surgical procedure known as a colostomy may be needed to correct an imperforate anus.

QUESTIONS TO ASK YOUR DOCTOR

- What is the prognosis for my child?
- What will daily life be like for my child throughout his or her life?
- What are the treatment options available to us?
- Is there genetic testing available to us if we decide to have more children?
- How often should my child be monitored for signs/symptoms related to this disorder?

Similarly, extra toes or fingers can be surgically corrected on an elective basis.

Seizures, such as those caused by gelastic epilepsy, may require symptomatic treatment.

Whenever a new case of PHS is uncovered, it is advisable to also examine the parents and any offspring for the disorder. Evaluation for a parent is likely to include a cranial MRI, x-rays of hands and feet, and laryngoscopy.

In 2015, a clinical trial on PHS was sponsored by the National Human Genome Research Institute (NHGRI), seeking to evaluate the range of severity, natural history, molecular etiology, and pathophysiology of PHS. Researchers were investigating the relationship between Pallister-Hall and some disorders with similar characteristics, including Greig cephalopolysyndactyly syndrome (GCPS), McKusick-Kaufman syndrome (MKS), Bardet-Biedl syndrome (BBS), and oro-facial-digital syndromes (OFDs).

Prognosis

Because of the broad range and severity of Pallister-Hall signs and symptoms, the prognosis varies widely from case to case, though only a small percentage are known to have serious complications.

In families in which multiple cases of PHS exist, the prognosis for any new case is likely to be similar to the existing cases. Mild forms of the syndrome have been identified in a number of large, healthy families whose members are believed to have normal life expectancies.

In cases that occur in isolated individuals, the prognosis is based on the specific malformations present. Reviews of these malformations as reported in scientific literature have limited usefulness because published cases tend to be more severe than those normally encountered.

Unless there are life-threatening malformations such as hypopituitarism, the prognosis for these random cases is considered excellent.

There is a 50% chance that any child of a Pallister-Hall patient will be affected.

Pallister-Killian syndrome

Definition

Pallister-Killian syndrome (PKS) is a rare chromosome abnormality in which a person has four copies of the short arm of chromosome 12 instead of the normal two copies. Affected individuals have unusual facial features, intellectual disabilities, seizures, patchy color differences in the skin, and various other physical

abnormalities. Many fetuses with PKS die during pregnancy or soon after birth.

Description

PKS was first described in 1977. The first two patients reported by Dr. Phillip Pallister, an American pediatrician and geneticist, were adults with severe intellectual disabilities, unusual facial features, severe lack of muscle strength, and pale areas on their skin. In 1981, Austrian Dr. Wolfgang Killian and his colleague Dr. Maria Teschler-Nicola described a child with intellectual disabilities, unusual facial features, pale skin on the face, and absence of hair at the front of the scalp.

PKS may also be called Killian syndrome, Killian/Teschler-Nicola syndrome, Pallister mosaic syndrome, or Teschler-Nicola/Killian syndrome. This syndrome is also known as tetrasomy 12p mosaicism or isochromosome 12p syndrome based on the characteristic chromosome abnormality detected via laboratory studies. PKS is called mosaic because the characteristic chromosome abnormality that causes the syndrome appears only in a fraction of the total cells examined.

Genetic profile

PKS is a sporadic disorder, which means that it appears to occur at random. The chromosome problem that causes PKS, tetrasomy 12p, does not appear to run in families. PKS is not specifically associated with any specific chemical or environmental exposures.

Tetrasomy 12p is characterized by the presence of four copies of the short arm of chromosome 12, instead of the normal two copies. This chromosome abnormality is not found throughout an affected person's body. Chromosome analysis performed on the blood of persons with PKS virtually always shows normal results. The characteristic chromosome abnormality can, however, be detected via chromosome analysis on skin cells. Through chromosome analysis, tetrasomy 12p is identified due to the presence of what appears to be an extra chromosome composed of two copies of the short arm of chromosome 12. This chromosome composed of two copies of the short arm of chromosome 12 is called an isochromosome. In tetrasomy 12p, there is a total of four copies of the short arm of chromosome 12: there are the two normal copies, plus the two abnormal copies located on the extra isochromosome.

Demographics

The incidence of PKS is uncertain and is estimated around 1 in 25,000. PKS occurs at random; however, an association with advanced maternal age (35 years or older) has long been documented. Though PKS may occur more frequently in babies born to mothers age 35

KEY TERMS

Bifid uvula—The uvula is the small, teardrop-shaped piece of flesh hanging in the back of the throat; the uvula is bifid if the bottom area is split in two parts.

Cystic hygroma—Birth defect that appears as a soft bulging under the skin at the neck; the bulging is actually abnormal growths of sac-like structures filled with lymphatic fluid.

Diaphragmatic hernia—An abnormal opening in the diaphragm, the layer of muscle that separates the chest cavity from the abdominal cavity.

Isochromosome—A chromosome is normally composed of two sections referred to as p and q; instead, an isochromosome is an abnormal chromosome made up of two p sections or two q sections.

Mosaic—Refers to a person or organ composed of two or more genetically different cell types.

Tetrasomy—Refers to the presence of four parts or copies of a chromosome or part of a chromosome.

or older, the syndrome still may occur in babies born to mothers of any age. PKS occurs strictly due to an abnormality of the chromosomes.

Signs and symptoms

Many infants with more severe physical defects associated with PKS die *in utero* or shortly after birth. Other persons with PKS have lived at least into their 20s. All persons with PKS have some level of intellectual disability or developmental delay.

The features of PKS may vary significantly between affected persons. The most typical person with PKS will have profound intellectual disabilities, delayed development, lack of muscle tone, light- and/or dark-colored areas of skin, lack of scalp hair above the temples, and unusual facial features. The facial features characteristic for PKS include a large forehead, widely spaced eyes with vertical folds of skin at the inner corners, droopy eyelids, short and upturned nose, full cheeks, lengthened distance between the nose and upper lip, and small chin.

Persons with PKS often have deafness, absent or minimal speech, poor vision, and seizures. Additionally, individuals with PKS have been reported as having short, wide hands with short fingers, while others have extra fingers or toes. Some affected persons have had cleft palate and some have had a bifid uvula (cleft, or split, uvula). The teeth come in later than normal in persons with PKS.

Heart defects may be present, and the sac normally surrounding the heart, the pericardium, may be missing. Additionally, there may be small patches of exposed tissue where the skin did not develop.

Many individuals with PKS have been reported to have extra nipples, and some have a hernia around the navel. Some persons with PKS have problems with the intestines or anus. Many have birth defects involving the genitals or internal reproductive organs and others have disorganized or cyst-filled kidneys. A small tail-like stub at the bottom of the spine was reported in at least one person affected with PKS.

The features of PKS change over time. The lack of hair above the temples, which is common in younger persons with PKS, mostly resolves by age five. Additionally, an affected individual's initial lack of muscle tone gives way to fixation of the joints later in life.

Diagnosis

PKS may be suspected from a person's physical features, but a diagnosis requires that a person has the characteristic chromosome abnormality, tetrasomy 12p. PKS is different from many types of chromosomal syndromes in that the causative chromosome abnormality is not found from chromosome studies on the blood. Chromosome testing on skin cells will show the characteristic chromosome abnormality in at least some of the cells. It is believed that the characteristic chromosome abnormality, the isochromosome 12p, does not show up in the blood cells because the abnormal isochromosome is lost in the rapid cell division that creates these blood cells. Diagnosis of PKS has traditionally required a skin biopsy, but recent reports indicate that the diagnosis can be made using cells scraped from the inside of the cheek.

Many cases of PKS may be diagnosed prenatally. PKS is detectable by amniocentesis, a routine test offered in pregnancies suspected to be at risk for chromosome problems. PKS may be suspected when certain physical abnormalities are detected on an ultrasound during pregnancy. In pregnancies where PKS has been diagnosed in an unborn baby, many ultrasounds have shown an increased amount of fluid around the baby, in addition to other physical abnormalities, including short arms and legs, heart malformations, diaphragmatic hernia, cystic hygroma, and unusually flat profile of the face.

Treatment and management

There is no treatment or cure for PKS or for the intellectual disabilities and developmental delays associated with this syndrome. Persons with PKS are treated for the symptoms they display. Individuals with PKS often take medications for seizures; some may have surgeries due

to birth defects involving the diaphragm, intestines, anus, kidneys, genitals, or heart. Physical therapy and occupational therapy may be helpful for development of muscle tone and reduction of joint fixation.

Prognosis

Many infants with PKS die before they are born (*in utero*), or soon after birth. Some affected individuals have been reported to live into their 20s. Many have severe to profound intellectual disabilities and have difficulties with self-care. A few reports have described affected persons with milder intellectual impairment.

Pancreatic beta cell agenesis

Definition

Pancreatic beta cell agenesis is a rare disorder in which a child is born with no beta cells—the cells in the pancreas that produce insulin—resulting in diabetes.

Description

Diabetes mellitus is a disease caused by elevated blood sugar and can result in numerous medical problems that can affect the kidney, eyes, cardiovascular system, skin, and joints. There are two common types. Type 1 results from the destruction of the insulin-producing cells (beta cells) of the pancreas and usually occurs in children of at least one year of age or young adults. Injected insulin is required to allow glucose (sugar) to enter the body's cells to be used for energy. Type 2 diabetes results from the body cells' decreased ability to respond to the insulin the body produces. In contrast to these two types, neonatal diabetes is extremely rare. Neonatal diabetes is usually transient, meaning that it goes away after some time. It appears to be caused by immaturity of the beta cells; about half of all babies with this form of the disease recover and do not require insulin earlier than three months of age. Fewer than 40 cases of permanent neonatal diabetes had been reported. Reported causes of neonatal diabetes have included absence of the whole pancreas, absence of the clusters (called islets) that contain the beta cells, and absence of the beta cells themselves. This last form is known as pancreatic beta cell agenesis.

Only one confirmed case of pancreatic beta cell agenesis has been reported (1993). This was in an infant girl who had a low birth weight and showed high glucose (sugar) in her blood during a routine test. She was pale, with a low body temperature, rapid breathing, and low muscle tone. Her health was further complicated by a diagnosis of an additional metabolic disorder, methylmalonic acidemia (MMA). She died at the age of 16 days. An autopsy showed that her pancreas had islets, which are the bundles of cells that typically contain insulin-producing cells as well as cells that produce other hormones. However, the islets in her pancreas did not contain the insulin-producing cells.

Genetic profile

Pancreatic beta cell agenesis may be an autosomal recessive disorder. This means that a child would have to inherit two abnormal copies of a specific gene, one from each parent, in order to have the disorder. The infant described had both pancreatic beta cell agenesis and MMA, also known to be an autosomal recessive disorder. A gene causing MMA is located on chromosome 6, and studies of this child's genes and chromosomes showed that she inherited two identical copies of at least part of chromosome 6 from her father, a condition known as paternal uniparental isodisomy, instead of one copy of this region from each parent. The MMA was caused by the inheritance of two identical abnormal *MMA* genes from her father, and the beta cell agenesis was then

KEY TERMS

Agenesis—Failure of an organ, tissue, or cell to develop or grow.

Beta cells—Specialized cells of the pancreas that make insulin.

Diabetes mellitus—The clinical name for common diabetes. It is a chronic disease characterized by inadequate production or use of insulin.

Insulin—A hormone produced by the pancreas that is secreted into the bloodstream and regulates blood sugar levels.

Metabolic disorder—A disorder that affects the metabolism of the body.

Metabolism—The total combination of all the chemical processes that occur within cells and tissues of a living body.

Pancreas—An organ located in the abdomen that secretes pancreatic juices for digestion and hormones for maintaining blood sugar levels.

believed to have been caused by the inheritance of two abnormal copies of another gene. On other chromosomes, it has been shown that certain genes work only when they come from the mother and others only from the father. Several cases of transient neonatal diabetes have also featured two identical copies of paternal chromosome 6 or other abnormalities of chromosome 6. This suggests that there may be a connection between pancreatic beta cell agenesis and transient neonatal diabetes. It is believed that the relevant region of chromosome 6 contains a gene that delays the production of insulin and works only when inherited from the father. As of 2015, there were no reports in the literature describing the status of the beta cells in infants with transient neonatal diabetes. Presumably, this is because a pancreatic biopsy would be required, and this procedure would be too strenuous for a fragile baby.

Demographics

The overall incidence of neonatal, or newborn, diabetes mellitus is approximately 1 in 400,000 to 1 in 600,000 live births, and many cases are transient, with the infants requiring insulin for an average of three months. These infants do appear to be at an increased risk of developing type 2 diabetes in young adulthood. Fewer than 40 cases of well-documented permanent neonatal diabetes have been reported. Only two infants with neonatal diabetes have demonstrated (by autopsy) a complete

lack of insulin-producing cells in the pancreas at birth. The first child had both pancreatic beta cell agenesis and another disorder called methylmalonic acidemia. She also had low birth weight, typical of children with neonatal diabetes because of the inability to metabolize glucose. The second child was of normal birth weight, suggesting that she originally had beta cells that were subsequently destroyed, perhaps by an autoimmune process as in type 1 diabetes. Both of these infants died in the newborn period.

Signs and symptoms

Symptoms of neonatal diabetes include lethargy, dehydration, and breathing difficulties. In the laboratory, high levels of glucose (sugar) in the blood and urine are demonstrated. Children with neonatal diabetes, including the child with pancreatic beta cell agenesis, are generally of low birth weight.

Diagnosis

Neonatal diabetes, like other forms of diabetes, is diagnosed by high blood sugar levels. Permanent and transient forms of neonatal diabetes are indistinguishable at initial diagnosis. Determining if the cause of neonatal diabetes is pancreatic beta cell agenesis was done after death in the published cases by studying the pancreas from an autopsy; a pancreatic biopsy would be required to make this diagnosis in a living child.

Treatment and management

Pancreatic beta cell agenesis, like type 1 and some cases of type 2 diabetes mellitus, is treated by insulin injection.

Prognosis

Both children that were reported to have an absence of beta cells were diagnosed through autopsy, because they died at birth. The second child's prognosis was complicated by the fact that she had the additional MMA disorder. As of 2015, it remained unknown if any living children had pancreatic beta cell agenesis.

Toni I. Pollin, MS, CGC

Pancreatic cancer

Definition

The pancreas is an important gland found in the abdomen behind the stomach. The pancreas secretes a fluid that breaks down fats and proteins and also releases hormones such as insulin to control blood sugar levels. Pancreatic cancer is the uncontrolled growth of malignant cells of the pancreas. A higher than average number of pancreatic cancer cases occurring in the same family is known as familial pancreatic cancer. However, according to the American Society of Clinical Oncology, more than 90% of families who meet the criteria for genetic testing for pancreatic cancer and have such testing will not have the mutation. This means that shared environmental factors also contribute to the risk for pancreatic cancer.

Description

Most pancreatic cancer grows from cells from the exocrine pancreas, the secreting portion of the pancreas. The most common appearance of pancreatic cancer cells is gland-like, which is termed adenocarcinoma. According to Natalia Khalaf and colleagues, more than 85% of all pancreatic cancers are adenocarcinomas.

In most cases, it is difficult to determine the cause of pancreatic cancer. Both environmental as well as genetic

risk factors have been implicated in pancreatic cancer. A high-fat diet has been linked to increased pancreatic cancer risk, whereas diets high in vegetables and fruits seem to lower the risk. Smoking is known to increase the risk of pancreatic cancer; it is estimated that as many as 20% of pancreatic cancer cases are linked to smoking. Smokeless tobacco products have also been associated with an increased risk for pancreatic cancer. Alcohol use has been linked with increased pancreatic cancer risk. Obesity is another risk factor for pancreatic cancer.

Certain occupations, such as farming or manufacturing, may increase the risk of pancreatic cancer. Multiple studies have shown that exposure to pesticides increases the risk. The relationship of diabetes to pancreatic cancer has been closely studied. It is uncertain whether diabetes is the cause or the symptom of pancreatic cancer. Long-term inflammation of the pancreas, chronic pancreatitis, increases the risk of pancreatic cancer. Genetic risk factors have also been reported.

Genetic profile

Several studies have reported a higher rate of pancreatic cancer in relatives of individuals with the disease. Characteristic features of a hereditary form of pancreatic cancer include having two or more first-degree relatives diagnosed with pancreatic cancer or one first-degree relative diagnosed with pancreatic cancer under the age of 50. Some risk is thought to be due to known hereditary conditions, whereas, in other cases, a known genetic syndrome has not been determined.

There are several known hereditary cancer syndromes that increase the risk of pancreatic cancer. Mutations in the *BRCA1* and *BRCA2* genes have been clearly

linked to increases in breast and ovarian cancer, as well as an increased risk for pancreatic cancer. Mutations in the *PALB2*, *FANCC*, *FANCG*, and *ATM* genes have also been linked to increased risks for pancreatic cancer. Changes, or mutations, in the *CDKN2A* (p16) gene responsible for familial atypical multiple mole melanoma syndrome (FAMMM) can increase risks of melanoma, a type of skin cancer, and also incur a 20-fold to 47-fold increased risk for pancreatic cancer. Hereditary nonpolyposis colon cancer (HNPCC), also known as Lynch syndrome, is caused by mutation in several genes, including the (*MLH1*, *MSH2*, *MSH6*, *PMS2*, or *EPCAM*) gene. These genes increase the risk for colon cancer and other cancers, including pancreatic cancer, in some families. Another colon cancer syndrome caused by mutations in the *APC* gene has been linked to pancreatic cancer. Peutz-Jeghers syndrome, juvenile polyposis syndrome (JPS), and Li-Fraumeni syndrome cause slightly increased risks of pancreatic cancer, in addition to the other symptoms of the disorders.

Another hereditary syndrome believed to be associated with pancreatic cancer is hereditary pancreatitis, caused by mutations in several different genes: *PRSS1*, *SPINK1*, and *CFTR*. Hereditary pancreatitis causes long-term, recurrent inflammation of the pancreas. Individuals with hereditary pancreatitis are estimated to have a 40% risk of pancreatic cancer by age 70.

All of these disorders are inherited in an autosomal dominant pattern. With autosomal dominant inheritance, men and women are equally likely to inherit the syndrome, and children of affected individuals are at 50% risk of inheriting the gene alteration.

Genetic testing is available for many of these known syndromes, but due to the complexity of the disorders, genetic counseling should be considered before testing. Some experts believe that the heritability of pancreatic cancer is as high as 21%. For example, in a study of nearly 3,568 people with pancreatic cancer and 3,363 controls, all of European descent and who were genotyped by Fei Chen and colleagues, the researchers found that chromosome 9 had the highest levels of genetic variations, followed by chromosomes 7, 8, and 1.

Some families with increased pancreatic cancer rates do not have a known genetic syndrome as the cause. It is possible that environmental factors or chance could explain some cases of pancreatic cancer in families; however, it is also possible that other as yet unknown genetic causes could explain some cases of familial pancreatic cancer. While genetic testing may not be available in all cases, families may participate in collections, or registries, of familial pancreatic cancer cases for research purposes.

Pancreatic cancer: pedigree analysis chart (Gale)

Demographics

The American Cancer Society (ACS) estimated that 60,430 people, including 31,950 men and 28,480 women, would be diagnosed with pancreatic cancer in 2021. The ACS also estimated the deaths from pancreatic cancer at 48,220 deaths in 2021, including 25,270 men and 22,950 women. Pancreatic cancer was the fourth leading cause of death in both men and women, representing 8% of all deaths from cancer in the United States in 2021. The ACS also estimates that the lifetime risk of a person in the United States developing pancreatic cancer is 1 in 64. Survival rates for pancreatic cancer depend on whether the cancer is localized, regional, or distant (metastasized far from the original tumor). For example, according to the ACS, the 5 year survival rate for localized cancer is 39%, while the regional survival rate in 5 years is 13%. However, many pancreatic cancers have metastasized at the time of diagnosis, and the 5 year survival rate at this stage is only 3%.

Signs and symptoms

Since the symptoms of pancreatic cancer typically do not develop until the cancer has progressed to an advanced state, it is difficult to diagnose pancreatic cancer at an early and much more treatable stage, and this is a key problem. In the future, genetic testing may identify individuals at risk for pancreatic cancer before they are symptomatic, so that these individuals can be closely followed and tested for possible cancer. For example, according to the American Society of Clinical Oncology (ASCO), all individuals with pancreatic adenocarcinoma should undergo genetic testing, as well as receive a complete review of their family cancer history. ASCO says

that up to 10% of all pancreatic adenocarcinomas are familial and some genes increase the risk for pancreatic cancer from 4 to 40%. Individuals with a known family history for pancreatic cancer should be carefully followed by their physicians. For example, the *BRCA2* gene, which is associated with cancer of the breast, ovary, melanoma, and the prostate, also increases the risk for pancreatic cancer. Some researchers are seeking laboratory or genetic markers that may indicate an increased risk for pancreatic cancer. For example, machine learning, also known as artificial intelligence, was engaged by Ananya Malhotra and colleagues in a study in which the medical records of about a thousand patients with pancreatic cancer over the period 2005-2009 were input to the computer, along with data from about 4,500 patients who did not have pancreatic cancer. The goal was to find patterns among the patients with pancreatic cancer, and 57 such patterns were found. The new data was able to correctly predict 41% of the patients at high risk for pancreatic cancer up to 20 months before their actual diagnosis. This information could not help patients who were already diagnosed, but it theoretically could help individuals in the general clinical population. The experts said that their algorithm could provide an early diagnosis in many patients with pancreatic cancer. The future goal is to apply this learned information to primary care patients not yet diagnosed with pancreatic cancer but who may be unknowingly at risk for the disease.

The symptoms of pancreatic cancer may include the following:

- unintended weight loss
- loss of appetite
- fatigue

- abdominal or back pain
- jaundice (yellowish color to skin and eyes)
- digestive problems, including greasy stool
- sudden diabetes onset
- nausea and vomiting

Diagnosis

If pancreatic cancer is suspected, a physical examination often is done first, and certain body imaging tests may be recommended. One imaging test that may be done is a computed tomography (CT) scan. This exam creates pictures of the interior of the body from computer-analyzed differences in x-rays passing through the body. Evidence of substantial tumors or any metastasis (spreading of cancer) can be detected by CT scanning. Once a biopsy is taken, the tissue sample is examined by CT for evidence of cancer and this typically determines the diagnosis.

Ultrasound is another method of viewing internal body structures. The type of ultrasound used to look at the pancreas (and other parts of the upper intestine) is called endoscopic ultrasonography (EUS). In ultrasound, sound waves are passed into the body and a computer develops an image based on the returned sound waves. Ultrasound is generally less expensive and more easily available than CT; however, there are limitations to the use of ultrasound in viewing the pancreas. Ultrasound may be used in addition to CT. MRI/magnetic resonance cholangiopancreatography (MCRP) and endoscopic retrograde cholangiopancreatography (ERCP) are methods of viewing the pancreas by inserting a thin tube down the throat, injecting of dye into the pancreatic and bile ducts, and visualizing with an MRI or an x-ray.

Once the tumor and any metastasis have been identified and the biopsy tissue evaluation has been done, the tumor can be staged. Staging is a ranking system that provides a method of describing the extent and characteristics of a cancer. Staging can be used to help determine the treatment and prognosis for a given cancer.

Unfortunately, it is very difficult to diagnose pancreatic cancer at an early stage, which makes screening for this cancer especially challenging.

Treatment and management

Surgery may provide the best chance of a cure, though surgery is not often possible due to the spread of cancer by the time it is diagnosed. Removal of all or part of the pancreas and other areas, such as the duodenum (the first part of the small intestine), is known as the Whipple procedure. Complications of this surgery

include infection and bleeding. Fewer than 20% of newly diagnosed pancreatic cancers are operable.

Chemotherapy is cancer-killing medicine that has been found to increase survival in some patients. This drug can be given intravenously or orally. Once in the bloodstream, chemotherapy agents reach other parts of the body. There are different chemotherapy agents and the side effects may be different as well, including nausea, hair loss, low blood counts, and other effects.

Recent improvements in radiation, high-energy rays directed at cancer cells, have made this therapy more effective. Although cures due to radiation therapy are uncommon, relief from pain and increased survival are possible. Side effects of radiation therapy may include skin changes, upset stomach, and other effects.

Sometimes, surgery, radiation, or other therapies are performed to relieve symptoms rather than cure the cancer. This is known as palliative treatment.

Involvement in research as part of clinical trials may be offered to certain patients. Although treatments through clinical trials may not be proven, it is an opportunity to potentially benefit from new therapies.

Illustration of pancreatic cancer and the location of the pancreas (between the stomach, liver, spleen, hepatobiliary system, and large and small intestines). Metastatic cancer is common among people with pancreatic cancer, most commonly spreading to the liver. (Molecule Medical Arts/ Science Source)

Pancreatic Cancer

Tumors are shown in reddish tint on the left end of the pancreas. The pancreatic duct is in green and the duodenum is reddish brown. (Spencer Sutton/Science Source)

Screening before cancer development may be considered for patients with a higher risk of the disease either due to a known genetic syndrome or to a family history of pancreatic cancer. ERCP, MCRP, and ultrasound have been used for screening purposes; however, the usefulness and cost-effectiveness of these tests for screening needs further evaluation. Surveillance may be considered for persons with two or more close relatives (first-degree family members) with pancreatic cancer, or with one close relative (first-degree) with pancreatic cancer at an early age (before age 50), or with two or more distant relatives (second-degree), one of which was affected before age 50.

Prophylactic pancreatectomy, surgical removal of the pancreas before any cancer development, has been considered in cases with a hereditary risk. The concern with prophylactic pancreatectomy is that there is a risk

of serious complications, and consequently the decision must be weighed carefully. Some experts are seeking possible preventive measures against pancreatic cancer; for example, Daoyan Wei and colleagues report that vitamin D supplementation is an area of current research in 2021. Many people with pancreatic cancer are deficient in vitamin D, which may be a related factor, and further research is needed.

Clinical trials

Clinical trials on pancreatic cancer are currently sponsored by the National Institutes of Health (NIH) and other agencies, such as the National Cancer Institute (NCI). In 2021, the NIH reported there were 890 active studies on pancreatic cancer, and many of these studies included screening, treatment, and genetic studies.

KEY TERMS

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes.

BRCA2—Gene, when mutated, known to cause increased risks of breast, ovarian, and, possibly, pancreatic cancer.

Cationic trypsinogen gene—Gene known to cause hereditary pancreatitis when significantly altered.

CDKN2A, or p16—Gene, when altered, known to cause familial atypical multiple mole melanoma (FAMMM) syndrome and possibly increased pancreatic cancer risk.

Chemotherapy—Treatment of cancer with synthetic drugs that destroy the tumor either by inhibiting the growth of the cancerous cells or by killing the cancer cells.

Computed tomography (CT) scan—An imaging procedure that produces a three-dimensional picture of organs or structures inside the body, such as the brain.

Duct—Tube-like structure that carries secretions from glands.

Duodenum—Portion of the small intestine nearest the stomach; the first of three parts of the small intestine.

Endoscopic retrograde cholangiopancreatography (ERCP)—A method of viewing the pancreas by inserting a thin tube down the throat into the pancreatic and bile ducts, injection of dye, and performing x-rays.

Exocrine pancreas—The secreting part of the pancreas.

First-degree relative—A closely related family member. Examples are parent/child, brother/sister, brother/brother, or sister/sister. First-degree relatives share 50% of their genes in common.

Hereditary nonpolyposis colon cancer (HNPCC)—A genetic syndrome causing increased cancer risks,

most notably colon cancer; also called Lynch syndrome.

Insulin—A hormone produced by the pancreas that is secreted into the bloodstream and regulates blood sugar levels.

Jaundice—Yellowing of the skin or eyes due to excess of bilirubin in the blood.

Li-Fraumeni syndrome—Inherited syndrome known to cause increased risk of different cancers, most notably sarcomas.

Melanoma—Cancerous tumor, usually of the skin.

Metastasis—The spreading of cancer from the original site to other locations in the body.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual or manifest as a disease and can be transmitted to offspring.

Palliative—Treatment done for relief of symptoms rather than a cure.

Pancreas—An organ located in the abdomen that secretes pancreatic juices for digestion and hormones for maintaining blood sugar levels.

Pancreatitis—Inflammation of the pancreas.

Peutz-Jeghers syndrome—Inherited syndrome causing polyps of the digestive tract and spots on the mouth, as well as increased risk of cancer.

Radiation—High-energy rays used in cancer treatment to kill or shrink cancer cells.

Second-degree relative—Two relatives (grandmother/father and grandchild or aunt/uncle and niece/nephew) who share 25% of their genes in common.

Staging—A method of describing the degree and location of cancer.

Whipple procedure—Surgical removal of the pancreas and surrounding areas, including a portion of the small intestine, the duodenum.

Examples include:

- RNA precision oncology in advanced pancreatic cancer. (NCT04476537)
- Systematic hereditary pancreatic cancer risk assessment and implications for personalized therapy. (NCT03060720)
- Biomarkers in patients with pancreatic cancer. (NCT03311776)

Clinical trial information is constantly updated by the NIH, and the most recent information on pancreatic cancer trials can be found at: <http://clinicaltrials.gov>

Prognosis

It is difficult to diagnose pancreatic cancer early, and, therefore, the cancer frequently has spread to other

QUESTIONS TO ASK YOUR DOCTOR

- What stage is my pancreatic cancer?
- What are the best treatment options for my newly diagnosed pancreatic cancer?
- Where can I learn more about clinical trials for pancreatic cancer patients, and how can I find out if I will qualify for a trial?
- Are there any screening options for healthy individuals with a known increased risk for pancreatic cancer?

locations in the body, such as the liver or lymph nodes (part of the immune system). Most long-term survivors originally had smaller tumors and no spreading of the cancer. Of course, every case of pancreatic cancer is different, and it is difficult to predict the course and survival for each individual patient. The prognosis of individuals with hereditary risk factors is dependent on the syndrome, if any, and the aggressiveness of the particular cancer.

Panic disorder

Definition

A panic disorder is a psychological state characterized by acute and rapid onset feelings that engulf and overwhelm the affected person with a deep sense of helplessness and impending doom. Panic disorder is an anxiety disorder characterized by worry and fear, as well as by physiological changes such as a rapid pulse and elevated blood pressure. The main feature of panic disorder (PD) is a history of previous panic attacks (PA). However, the first time individuals experience a panic attack, they may feel certain they are having a heart attack and risking death. As a result, they often present to a hospital emergency room, where they are evaluated for a possible heart attack, cleared from that diagnosis, and diagnosed instead with a panic disorder (PD). PA symptoms are pronounced, and the affected person may gasp for air, have a rapid rate of breathing (hyperventilate), feel dizzy or light-headed, and develop a loss of sensation (paresthesia). Most panic attacks last three to ten minutes, and it is rare for one to extend in duration more than 30 minutes.

Description

The essential characteristics of panic disorder (PD) consist of specific and common criteria. The affected person usually has recurrent, uncontrollable, and unexpected panic attacks, which are the active presentation of panic disorder. The panic attack is characterized by a discrete, rapid onset of feeling intense fear or discomfort and a feeling of unreality. Affected persons have several physical signs and cognitive symptoms, and they usually react in a manner showing fear of imminent death or disaster. Individuals having a PA commonly exhibit signs of heavy sweating, a racing heartbeat, chest pain, shortness of breath, and the perception of feeling smothered. The PA is usually followed by a period of one or more months of thought processes that focus on irrational fears.

Genetic profile

Panic disorder can run in families, and twin studies suggest that about 20% of patients who meet the criteria for diagnosis have first-degree relatives with the disorder. In families with no history of affected first-degree relatives, the prevalence decreases to 4%. The ratio between monozygotic twins (identical) to dizygotic (nonidentical) twins is 5:1 for PD. British researchers have also found more than 500 genes linking anxiety and depression in some individuals, and this genetic finding affects at least 1.4 million people in the United Kingdom who report suffering from both depression and anxiety. Recent evidence suggests that there is a genetic mutation in the *SLC6A4* gene. This gene encodes for a molecule that is related to a brain chemical called serotonin, which is known to affect mood. If the transport of serotonin is imbalanced, certain parts of the brain may not receive the correct stimulus, causing alterations in mood.

Another gene possibly associated with PD is the *COMT* gene that encodes the enzyme catechol-O-methyltransferase. Mutations in this gene have been associated with other disorders that affect thought and emotion, with studies suggesting that these conditions may be due to inefficient degradation of catecholamines, a family of neurotransmitters that include adrenaline and dopamine.

Demographics

PD usually begins during the affected person's late teens or 20s and is uncommon after the age of 35 years. Global studies suggest that the lifetime prevalence of PD is between 1.5% and 3.5% of the population. In the United States, the National Institute of Mental Health (NIMH) estimates that about 12.5 million American adults have ever experienced a PA, and PD is twice as common in women as men.

Agoraphobia (an anxiety state about being in situations or places that might make escape embarrassing or difficult) is seen in approximately one-third to one-half of persons who meet the criteria for PD diagnosis. Other reports indicate that about 95% of persons affected with agoraphobia also have a previous history or current diagnosis of PD.

Signs and symptoms

Criteria for panic disorder

- Recurrent and unexpected PA.
- Worry about the consequences, implications, or behavioral changes associated with PA.
- PA is not caused by, or associated with, a medical condition. It is not associated with another mental disorder, such as phobia (an exaggerated fear of something like spiders or heights).
- Exposure to a specific phobia situation or object can promote a PA.

Criteria for panic attack

- Cardiac palpitations (pounding, racing, or accelerated heart rate)
- Sweating
- Shaking (trembling)
- Breathing difficulties, including shortness of breath or perceptions of being smothered
- Feeling of choking
- Chest discomfort or pain
- Feeling light-headed (faint, dizzy, or unsteady)
- Stomach discomfort or nausea
- Loss of contact with reality during the attack
- A feeling of being detached and out of contact with oneself
- Fear of losing control of oneself (going "crazy")
- Fear of dying
- Tingling or numbness sensations

Criteria for agoraphobia

The essential feature of agoraphobia is anxiety about being in situations or places that make escape embarrassing or difficult. These fears usually involve characteristic clusters of situations that include being on a bridge, being in a crowd, standing in line in a department store, or traveling in a train, bus, or automobile. Elevators are another common cause promoting the occurrence of PA. These situations, which lead to the PA, are often difficult or embarrassing to flee from abruptly. Avoidance of the

affected person's fear, which usually limits travel away from home, causes impaired functioning.

Criteria for PD without agoraphobia

Recurrent unexpected PA is characterized by at least one attack, followed by a month or more of one or more of the following symptoms:

- Persistent concern about having future attacks
- Worry about consequences associated with attacks
- A change in behavioral patterns related to the attacks (e.g., the affected person avoids travel)
- Absence of agoraphobia
- PA not due to a medical condition
- PA not associated with another mental disorder (e.g., phobias)

Diagnosis

There are no specific laboratory findings associated with diagnosing PD. However, evidence suggests that some affected persons may have low levels of carbon dioxide and an important ion in the human body called bicarbonate that helps in regulating blood from becoming too acidic or alkaline. These chemical changes may hypersensitize nerve cells, which can increase the activity of other structures throughout the body, such as sweat glands and the heart and therefore contribute to symptoms of PD. Additionally, lactic acid (a chemical made in the body from sugar) plays a role in nerve cell hypersensitivity. The diagnosis of PD can be made accurately if the specific symptoms and criteria are established.

Neuroimaging studies indicate that the arteries, the vessels that deliver oxygen-rich blood to cells and tissues, are constricted as a result of increased breathing rates during a PA. The consulting clinician must exclude other possible causes of panic attacks, such as intoxication with stimulant drugs such as cocaine, caffeine, and amphetamines. Withdrawal from alcohol and barbiturates can also induce panic-like behaviors. Additionally, the consulting therapist should obtain a comprehensive medical history and examination to determine whether the PA is caused by a medical condition frequently observed in hormonal diseases like overactive thyroid or tumors that secrete chemicals causing a person to have pronounced "hyper" changes like racing heartbeat, sweating, and shaking. Other causes include a possible cardiac disease, such as arrhythmia, when the heart beats irregularly.

Treatment and management

Moderate to severe PD is characterized by frequent PA ranging from five to seven times per week or with significant disability associated with anxiety among

KEY TERMS

Cognitive-behavioral therapy—A therapy technique that works toward diminishing the irrational fears that are causing panic attacks by confronting the triggers that cause the attacks. Therapy includes breathing techniques and noting physical changes and sensations during anxiety and attacks.

Palpitation—An irregular heartbeat.

Phobia—An exaggerated fear.

Recurrent—Tending to repeat.

episodes. In addition to cognitive-behavioral therapy (CBT), an affected person will usually require medications. There are four classes of medications commonly prescribed for PD patients.

Tricyclic antidepressants

Tricyclic antidepressants are a class of older medications used to treat depression and other closely related mental disorders such as PD. Individuals affected with PD who are treated with tricyclics are usually given imipramine, which has been shown in some studies to be effective in approximately 70% of cases. Medications in this category usually have a prolonged lag time until a positive response is observed. This is primarily due to adverse side effects, which prevent rapid increases of dosage, and also because they act on specific chemical imbalances in the brain that take time to stabilize.

Choices of tricyclic antidepressants for PD may include imipramine, desipramine, and nortriptyline. These medications require careful dosing and monitoring. The actual dosage can vary from case to case. Elderly patients may require a smaller dose due to decrease in metabolism of large chemicals and in kidney function, which are part of aging. Some patients may develop gastrointestinal side effects, which may interfere with absorption from the gut, thereby decreasing beneficial blood levels. More common side effects experienced by patients who are prescribed tricyclics are dry mouth and low blood pressure. The heart may be adversely affected, especially in patients with pre-existing diseases, causing direct damage or strain on the heart. People taking tricyclics also commonly experience changes in sexual functioning. Adverse side effects can make patients not want to take the medication at its proper dosage, which decreases its effectiveness.

Selective serotonin reuptake inhibitors

A newer group of antidepressants compared to tricyclics, the selective serotonin reuptake inhibitor

(SSRI) is another medication option. Some SSRIs are approved by the Food and Drug Administration (FDA) to treat panic disorder, including fluoxetine (Prozac), paroxetine (Paxil), and sertraline (Zoloft). These medications act on specific areas in the brain to brain levels of serotonin, a neurotransmitter. However, as with all medications, SSRIs have potential side effects, such as nausea, difficulty sleeping, sweating, fatigue, and sexual problems.

Monoamine oxidase inhibitors (MAOIs)

A second line category of medications used to treat PD is the monoamine oxidase inhibitors (MAOIs). Monoamine oxidase is a protein that assists in storing certain chemicals in nerve cells. MAOIs will stop the action of this protein, thereby decreasing the amount of certain chemicals in the brain that may influence PAs. This group of medications is effective in approximately 75% to 80% of cases, especially for nonactive depression. Affected individuals using MAOIs must avoid specific foods in order to prevent a hypertensive crisis (when the blood pressure rapidly increases). These foods include some cheeses, liver of all types, meat and yeast extracts, fermented or aged meats like salami and bologna, broad and Chinese bean pods, all types of alcohol-containing products, soy sauce, shrimp and shrimp paste, and sauerkraut. Although MAOIs are effective medications for treatment of PD, they are underutilized due to strict dietary limitations.

Benzodiazepines

Benzodiazepines are another class of medications used to treat PD; however, these drugs carry a risk for addiction according to the Drug Enforcement Administration (DEA). They are also sedating medications, and individuals who take them should not drive or engage in arduous or challenging tasks. Individuals who have issues with alcohol or drug abuse should avoid these medications, which may interact with other drugs. They include medications such as alprazolam (Xanax), diazepam (Valium), lorazepam, (Ativan) clonazepam (Klonopin), and others. Benzodiazepines have been reported to be effective in 70% to 90% of patients with PD; however, the effective dose of shorter-acting drugs is approximately two to three times higher for PD than for milder forms of simple anxiety, and these medications are usually indicated for mild anxiety. This increased dosing in patients with PD is undesirable, since there is risk of physical dependence and withdrawal, commonly exhibited when the medication is rapidly tapered down or stopped. However, they are indicated when PD-affected patients respond poorly to tricyclics or have a fear of taking MAOIs due to dietary restrictions and problems associated with eating the wrong foods accidentally. Some

researchers have tested experimental drugs for panic disorder, such as orexin receptor (OXR) antagonists, with promising results.

Long-term management

Reassuring the PD patient that anticipated panic attacks are unlikely while taking medication is essential for long-term maintenance. Cognitive-behavioral therapy is also important for long-term treatment. Weaning off medications must be done slowly, since patients develop a sense of security that they will not have an attack while decreasing their dosage. It is also best if people with PD avoid caffeine, because researchers have found that nearly half of those with PD are triggered by caffeinated beverages or foods. Coffee and tea contain caffeine, as do chocolate and many soft drinks.

Clinical trials

The National Institutes of Health (NIH) and other agencies currently sponsor clinical trials on panic disorder. In 2021, NIH reported 200 ongoing and completed studies, including:

- The role of Orexin in human panic disorder. (NCT02593682)
- The effect of transcranial direct current stimulation in panic disorder (PDstim). (NCT04160806)
- Breathing regulation training for individuals with panic disorder. (NCT00183521)
- Changes of cerebral glucose metabolism after 12 weeks of paroxetine treatment in panic disorder. (NCT00767754)

Clinical trial information is constantly updated by the NIH, and the most recent information on panic disorder trials can be found at: <http://clinicaltrials.gov>.

Prognosis

The courses of PD and agoraphobia vary considerably over time. Some affected people may experience spontaneous remissions, where the disorder is present but not active. The course of PD can be so variable that an affected person may go on for years without a PA, have several attacks, and then enter a second phase of remission that may last for years. In some cases, a decrease in PA may be closely related to a decrease and avoidance of anxiety-associated situations that promote agoraphobia. Agoraphobia itself may become chronic with or without PA. In general, approximately 50% to 60% will recover substantially five to 20 years after the initial attack. Approximately 20% will still have long-term impairment, which will stay the same or worsen slightly. Generally, the earlier treatment is sought, the better the outcome. The course in children and

QUESTIONS TO ASK YOUR DOCTOR

- Are the symptoms I have described typical of panic disorder?
- If my spouse and I decide to have children, are they likely to inherit this condition from one of us?
- What medications are appropriate to relieve the symptoms I am experiencing from panic disorder?
- What side effects, if any, should I expect from these medications?

adolescents is chronic, usually lasting about three years. Generally, PD shows the highest risk of developing new psychological disorders during follow-up visits. If PA is treated early, anticipatory anxiety and phobia may be more manageable and responsive to treatment.

Pantothenate kinase-associated neurodegeneration

Definition

Pantothenate kinase-associated neurodegeneration (PKAN) is a genetic disorder of the nervous system. It is characterized by prolonged movement difficulties and an accumulation of iron in the brain.

Alternate names associated with pantothenate kinase-associated neurodegeneration include neurodegeneration with brain iron accumulation (NBIA), juvenile-onset neuroaxonal dystrophy, Hallervorden-Spatz syndrome or disease, and hypoprebetalipoproteinemia, acanthocytosis, retinitis pigmentosa, and pallidal degeneration (HARP). Hallervorden-Spatz disease and HARP were once considered separate disorders. HARP is now considered to be a part of PKAN, and both are associated with dysfunction of movement, dementia, and eye disorders.

Description

PKAN is a genetic disorder that usually results when an individual inherits a mutation in a gene that makes a protein called pantothenate kinase 2. Ten gene mutations have been identified that cause this disorder. Eight are autosomal recessive, one is autosomal dominant, and

one is X-linked dominant. These mutated genes cause iron to build up in parts of the brain, particularly in the basal ganglia. This region is a collection of three clusters of nerve cells (neurons) that control movement. These three clusters are known as the caudate nucleus, putamen, and globus pallidus and are located deep in the brain. When iron accumulates in the basal ganglia, involuntary movements can result. These include tremors and jerking movements or rigidity of the limbs.

Two forms of the disease exist:

- Classic form, in which symptoms arise in early childhood. Symptoms are usually severe and worsen rapidly.
- Atypical form, which appears later in childhood or in adolescence. Symptoms are generally less severe and advance more slowly than those in the classic form. The atypical form is less common than the classic form.

Genetic profile

PKAN results from a mutation in the *pantothenate kinase 2* gene, which is generally abbreviated *PANK2*. This disorder is an autosomal recessive one, so it occurs when an individual inherits a mutated *PANK2* gene from each parent. The parents may not have the condition themselves but may instead only be carriers. A carrier is an individual who does not develop the disorder but may pass the gene for the disorder onto a child. If both parents are carriers, each of their children has a 50% chance of being a carrier and a 25% chance of acquiring the disorder. If both parents have PKAN, all of their children will also acquire the disorder.

Located on the short arm of chromosome 20, the *PANK2* gene carries the blueprint for making the enzyme pantothenate kinase 2, which is active in the mitochondria (the powerhouses of cells) in nerve cells within the brain. Pantothenate kinase 2 is part of the process that makes the molecule called coenzyme A, which is important in converting carbohydrates and fats into energy.

Individuals who have inherited the mutated *PANK2* gene from both parents experience a disruption in the production of coenzyme A, iron begins to accumulate in the brain, and a range of symptoms develop.

Scientists know of some 100 different mutations in the *PANK2* gene that are associated with PKAN. Commonly, the *PANK2* mutation results from a substitution in amino acids, the building blocks of proteins. The amino acid glycine is often substituted with the amino acid arginine at a single position in the enzyme. In some patients, usually including those with the classic form of the disease, the mutation completely cuts off production of functional pantothenate kinase 2. In other patients,

usually those with the atypical form of the disorder, the enzyme is produced, but it does not function as it should. Either way, the manufacture of coenzyme A is compromised, and symptoms arise.

Demographics

PKAN is estimated to affect 1 to 3 people per million (an incidence rate of 0.001%–0.0003%). Its incidence does not appear to be related to ethnicity, gender, or geographic area. The classic form is more common and accounts for about three-fourths of all cases.

Signs and symptoms

Individuals with PKAN typically begin to experience symptoms as children, and they worsen as they age. Symptoms may include the following:

- Involuntary muscle contractions (dystonia)
- Tremors
- Muscle spasms
- Stiffness or rigidity in the arms and legs
- Difficulty walking
- Weakness
- Abnormal posture
- Repeated words, rapid speech, or slurred speech, particularly in the atypical form
- Swallowing problems (dysphagia)
- Night blindness followed by increasingly impaired vision
- Dementia
- Behavioral problems, particularly in the atypical form
- Personality changes, particularly in the atypical form
- Depression, particularly in the atypical form

Diagnosis

Patients and/or their parents should inform the doctor of any family history of this (and other inherited neurological or muscular disorders), which will be helpful in making a diagnosis.

Examination

The doctor will typically conduct or order a neurological examination to check for muscle weakness, rigidity of the limbs, involuntary muscle contractions, and other movement abnormalities.

Tests

Although not widely available, genetic testing can confirm the presence of the mutation associated with PKAN.

QUESTIONS TO ASK YOUR DOCTOR

- Who is at risk for PKAN/NBIA disorders?
- What treatment options do I have if I am diagnosed with PKAN/NBIA?
- What changes can I make in my lifestyle to help diminish the effects of the disorder?
- Should I seek genetic counseling before deciding to have children?

Procedures

A particularly telling diagnostic tool for this disorder is a magnetic resonance imaging (MRI) scan, which can detect a pattern of iron accumulation in the brain that is characteristic to this disorder. This pattern is known as the *eye of the tiger*.

Treatment and management

No cure for PKAN is available, but treatments exist for a number of the symptoms. Some are as follows:

- Nerve-blocking botulinum toxin, the muscle relaxant baclofen, or other surgical treatments for dystonia
- Evaluations and possible treatments for feeding problems
- Pain medications when necessary

In addition, recent clinical trial results have shown efficacy of Deferiprone (an iron chelator) in decreasing iron accumulation in the brain and improving the motor function in patients with NBIA. Medical professionals may also recommend physical therapy for movement issues or occupational therapy to assist the day-to-day life of those individuals who have visual, motor, or other impairments. There is no way to prevent PKAN. It is an inherited disorder.

Adults who are carriers may wish to undergo genetic counseling before deciding to have children so that they understand the risks. Brothers and sisters of a child with the disorder have a 25% chance of having the disorder themselves, and a 50-50 chance of being a carrier for the disorder.

Prognosis

Individuals with the classic form of this disease generally experience their first symptoms before they reach ten years of age, whereas those with the atypical form usually do not have symptoms until they are more than ten years of age, sometimes not until they reach their

20s. In both cases, the disease worsens over time, but the classic form progresses more quickly. In individuals with the classic form, the ability to walk on their own is lost within 10 to 15 years of the onset of symptoms. Those with the atypical form generally lose the ability to walk unassisted within 15 to 40 years after the onset of symptoms. Many individuals with this disorder live long lives, but some die young due to secondary problems (such as aspiration pneumonia that results from inhaling an inappropriate substance such as saliva or vomit) associated with the illness.

Parkes Weber syndrome

Definition

Parkes Weber syndrome is a disorder of the vascular system characterized by anomalies in the arteries and veins that can cause skin discoloration, disproportionate growth of one limb compared to the other, and, in the

most serious cases, heart failure due to poor regulation of blood flow.

Description

British dermatologist Frederick Parkes Weber first described Parkes Weber syndrome in 1907. The syndrome is characterized by the occurrence of vascular anomalies called capillary malformations and arteriovenous fistulas (AVFs). Capillary malformations increase blood flow to the surface of the skin, producing large, flat splotches on the skin that are often referred to as port wine stains due to their pink-to-red color. Slow-flowing capillary lesions that dilate or increase in number near the surface of the skin cause these stains. AVFs are faulty connections between arteries and veins that can cause bleeding in the skin, muscle, bone, brain, and other organs. This bleeding can have dangerous neurological effects and can also lead to heart failure, making Parkes Weber syndrome a potentially life-threatening disorder. These malformations are usually present at birth and can progress during development.

In some cases, one limb can grow larger than the other; most commonly this occurs in the leg. This deformity is due to uneven growth in the soft tissue of the legs.

Genetic profile

Parkes Weber syndrome can be caused by mutations in the *RASA1* gene, which codes for the p120-RasGAP protein. The Ras genes code for a family of GTPase proteins that are involved in the regulation of cell division and differentiation in a number of tissue types, including blood vessels. GTPases are enzymes that hydrolyze the molecule GTP to provide energy for molecular interactions and protein activity. The activity of Ras proteins is modulated by GTPase activating proteins (GAP) that serve as enhancers for the GTPase protein function. The *RASA1* protein is a GAP that modulates Ras GTPases and is involved in regulating Ras activity during cell development.

Mutations in *RASA1* can be inherited, normally in an autosomal dominant pattern, but they can also occur in individuals with no family history of the syndrome. Because some cases of Parkes Weber syndrome are caused by other, unknown genetic mutations, occurrence of the disease is often sporadic and difficult to predict.

Demographics

Parkes Weber syndrome is very rare, and the prevalence is unknown; however, it is estimated that it may affect approximately 0.3% of the world's population.

KEY TERMS

Artery—A blood vessel that carries blood away from the heart to peripheral tissues.

Capillary—A very narrow tube that carries liquid like blood or lymphatic fluid.

Debulking—The removal of abnormal tissue.

Lesion—A defective or injured section or region of the brain (or other body organ).

Vascular system—The network of blood vessels in the body.

Vein—A vessel that carries oxygen-poor blood from the tissues and extremities back toward the heart to be reoxygenated.

Signs and symptoms

The presence of capillary malformations and AVF are what distinguishes this congenital vascular syndrome from other, similar disorders. Parkes Weber syndrome is potentially more serious than similar disorders because of the stress AVF and the increased blood flow to overgrown limbs can put on the heart.

Klippel-Trenaunay syndrome (KTS) is another congenital vascular disorder that has similar symptoms to those of Parkes Weber syndrome but is less life-threatening. KTS also presents with port wine stains and increased growth of bone and soft tissues, but not AVF. Capillary malformation-arteriovenous malformation (CM-AVM) also has similar vascular abnormalities to those of Parkes Weber syndrome. Similarities in genetic anomalies or mutations between all three syndromes may be the reason for the overlap of symptoms.

Diagnosis

The diagnosis for Parkes Weber syndrome is based on clinical and molecular genetic testing. Since mutations in *RASA1* are known to cause the syndrome, individuals who are suspected to have it can be tested directly for changes in the *RASA1* gene.

Treatment and management

There is no one treatment regimen generalized for all patients with Parkes Weber syndrome because the symptoms can be complex and vary in severity. Most treatments are considered on a case-by-case basis depending on the individual condition. In some cases, debulking can remove excess or damaged vasculature. This can decrease or limit problematic blood flow or lesions. Debulking is invasive

QUESTIONS TO ASK YOUR DOCTOR

- Why is Parkes Weber syndrome more dangerous than other vascular disorders?
- Can I pass this disease to my children?
- What tests or other procedures are used to diagnose this condition?
- Can Parkes Weber syndrome be cured and, if not, what kinds of treatment are available?

and can cause complications; therefore, it is often used only as a last resort. There is also a high rate of recurrence of lesions, and in the long term, debulking may not have a lasting benefit to the patient. In the most extreme cases where tissue or limbs are compromised by the vascular abnormalities, amputation is utilized. This was more common in the early days of treatment and is now avoided as much as possible.

Nonsurgical treatment options include sclerotherapy, in which medicines are injected into affected vessels to shrink them and allow for more normal blood flow. Compression therapies and garments can alleviate blood flow impediments, providing pain relief and decreasing some risks of infection that are linked to inflammation and circulation problems. Combined with elevating the affected areas, compression therapy can be useful in the management of discomfort caused by the symptoms of Parkes Weber syndrome.

Prognosis

While the symptoms can be treated, there is no cure for Parkes Weber syndrome.

Parkinsonism see **Parkinson's disease**

Parkinson disease—juvenile see **Parkinson's disease**

Parkinson's disease

Definition

Parkinson's disease (PD) is a progressive neurological movement disorder that can cause tremors, slow movement (bradykinesia), rigidity, and balance problems. It can also cause memory problems, depression, and other symptoms. PD results when the brain cells (neurons) that make the chemical dopamine die or stop working. Dopamine is a neurotransmitter that sends signals to other nerve cells (neurons).

Description

PD was first noted by British physician James Parkinson in the early 1800s. It is a degenerative neurological disorder that causes movement problems like tremor, slowness, stiffness, and walking and balance problems. It causes a progressive decline in movement control, affecting the ability to control initiation, speed, and smoothness of motion. It is associated with a variety of other symptoms like depression, memory problems, and effects on the automatic functions that our body performs. PD is associated with aging, and symptoms are seen in up to 15% of people aged 65 to 74 and almost 30% of people aged 75 to 84.

PD affects the basal ganglia and substantia nigra of the brain. Nerve cells (neurons) in the substantia nigra, which produce dopamine, are responsible for passing on messages that control movement. In a person with PD, dopamine-producing neurons of the substantia nigra die off or stop working properly. The dying brain cells contain Lewy bodies, which can help with diagnosing PD. PD symptoms occur when around 80% of dopamine is lost. When that happens, dopamine receptors in the central part of the brain called the striatum are not properly stimulated, which causes the basal ganglia of the brain to become over- or under-stimulated. When it is over-

stimulated, tremors result. When it is under-stimulated, slowness of movement and rigidity result. What causes the neuron death is largely unknown.

When no cause for nigral cell degeneration can be found, the disorder is called idiopathic Parkinsonism, or Parkinson's disease (PD). Parkinsonism symptoms may be seen in other degenerative conditions, known as the "Parkinsonism plus" syndromes, such as progressive supranuclear palsy.

Usually, PD only happens in one family member. Only about 15% of people with PD have a familial form in which multiple family members are affected. Late-onset adult PD is the most common type of PD, and it usually starts in the late 50s or early 60s. About 10% to 20% of people have an early-onset type of adult PD before the age of 50. Juvenile-onset PD usually starts before age 20. The early-onset adult and juvenile types of PD are more likely to result from a pathogenic variant in a single gene (mutation).

Genetic profile

For most people, the cause of PD is unknown, but it seems to result from a combination of genetic and environmental factors. About 5% to 10% of people with PD have monogenic PD, meaning that it is caused by a pathogenic variant in a single gene. There are a number of different genes that cause monogenic PD.

Monogenic PD is usually inherited in an autosomal dominant or autosomal recessive manner. Rarely, it can be inherited in an X-linked manner. Someone with autosomal dominant PD has a pathological variant (mutation) in one copy of a PD gene and one copy without a variant. They have a 50% chance of passing PD on to their children. Someone has autosomal recessive PD if both copies of their PD gene have a variant. Autosomal recessive PD can only be passed on if both parents are at least carriers, meaning that they have a variant in one copy of the same PD gene. Two carriers have a 25% chance of having a child with PD. X-linked PD results from a variant of a PD gene on the X chromosome. Males have one X chromosome and one Y chromosome, while females have two X chromosomes. X-linked PD usually affects males who inherit the variant from their mother. Carrier females who have one copy with a variant and one normal copy usually do not have symptoms. Carrier females have a 50% chance of passing it on to their children. Daughters born to fathers with X-linked PD will all be carriers, and sons will not have a PD variant.

Monogenic Early and Late Onset PD (Adult Onset)

The most common monogenic genes that cause adult onset PD are:

Degeneration of dopaminergic neurons in the substantia nigra of the midbrain. The image at top depicts where the substantia nigra lies in the brain. At bottom right is a normal substantia nigra and at bottom left is a diminished substantia nigra. Degeneration of this structure is characteristic of Parkinson's disease. (Monica Schroeder/ Science Source)

- PARK-GBA, found in 3% to 7% of adult onset PD and 20% of adult onset PD in those of Ashkenazi Jewish ancestry.
- PARK-LRRK2, found in 1% to 2% of adult onset PD and 13% to 30% of adult onset PD in those of Ashkenazi Jewish ancestry and 41% in those of African Berber ancestry.
- PARK-PINK1 found in 3.7% of early onset adult PD
- PARK-Parkin found in 1% of adult onset and 4.6% to 10.5% of early onset adult PD

Monogenic Juvenile Onset PD

Monogenic Juvenile Onset PD is usually inherited in an autosomal recessive manner where both parents are carriers of a variant of a PD gene. Two carriers have a 25% chance of having a child with PD. Variants in at least six genes can cause monogenic juvenile onset PD. Each of these variants is rare.

Susceptibility Genes for PD

There are also gene variants that appear to play a smaller role in predisposing people to PD. Unlike the genes that cause monogenic PD, these genes may slightly increase the lifetime risk of PD or may influence things

like age of onset and the progression of the symptoms. Most of these genes are still being researched and are not typically included in clinical genetic testing or diagnosis of PD.

Environmental risk factors in PD

Increasing age is one of the most important environmental risk factors for PD. Aging causes a normal decline in dopamine-producing neurons. It is possible that some people who develop PD at an older age are born with fewer dopamine-producing neurons and are therefore more susceptible to age related PD. Environmental risk factors decrease the number of dopamine neurons, making the brain more susceptible to the age-related decline in neurons.

Some environmental risk factors that seem to increase the risk of PD are: pesticide exposure, head injury, rural living, and infectious agents. A chemical called MPTP, which is found as an impurity in some illegal drugs, can cause permanent symptoms of PD within hours of ingestion. MPTP may exert its effects through generation of toxic molecular fragments called free radicals. Reducing free radicals has been a target of several experimental treatments for PD using antioxidants. Some environment factors that seem to decrease the risk of PD are: tobacco smoking, caffeine, use of nonsteroidal anti-inflammatory drugs like ibuprofen, high blood urate levels, and physical activity.

Demographics

PD affects approximately 500,000 people in the United States—both men and women—with as many as 50,000 new cases each year.

Signs and symptoms

Different people with PD have different symptoms. Some are obvious, and others are hard to detect. People with PD often have motor symptoms that are related to movement and other non-motor related symptoms. People with juvenile-onset PD often have involuntary muscle contractions (dystonia), abnormal muscle tightness (spasticity), and dementia.

Motor Symptoms

The three main motor symptoms of PD are

- **Resting tremors:** a rhythmic, involuntary shaking that occurs in a finger, hand, arm, or leg when it is at rest. It usually disappears during voluntary movement. The classic tremor of PD is called a “pill-rolling tremor” because the movement resembles rolling a pill between the thumb and forefinger.

- **Slow movements (bradykinesia)** occur, which may involve slowing down or stopping in the middle of familiar tasks such as walking, eating, or shaving. They may include freezing in place during movements (akinesia).
- **Muscle rigidity or stiffness**, occurring with jerky movements replacing smooth motion. This can also result in a “masked face,” with little facial expression and decreased eye-blinking.

Everyone with PD has bradykinesia, but they might not have the other two motor symptoms. Tremor is the most common symptom when PD is diagnosed, but not everyone with PD has tremor. Some people with PD have problems walking or difficulties with balance and coordination, which may lead to a rapid, shuffling gait (festination) to prevent falling. Usually these happen later on as the disease advances.

Non-motor Symptoms

People with PD can experience a wide-range of non-motor symptoms, which are very common and can affect

Colored 3D magnetic resonance imaging (MRI) scan of the brain of a patient who has had an electrode (grey line) inserted into the brain. The electrodes stimulate the brain to help to control the tremors associated with Parkinson's.
(Zephyr/Science Source)

Illustration of a brain with Parkinson's disease. (J. Bavosi/ Science Source)

almost every part of the body and can happen at any time. The severity of these symptoms varies from person to person. Some of the non-motor problems can be:

- Mood and thinking problems. Like depression, anxiety, lack of motivation and interest in activities, memory or thinking problems, and hallucinations or paranoid beliefs.
- Effects on the automatic functions that our body performs: constipation, low blood pressure, sexual problems, excessive perspiration, and problems with urination.
- Other physical changes like drooling, sleepiness, speech problems, pain, skin changes, sleep problems, loss of smell, swallowing problems, vision problems, and weight loss.

Diagnosis

The diagnosis of PD involves a careful medical history and a neurological exam to look for characteristic symptoms. There are no definitive tests for PD, although a variety of lab tests may be done to rule out other causes of symptoms, especially if only some of the major symptoms are present. Tests for other causes of Parkinsonism

symptoms may include brain scans, blood tests, lumbar puncture, and x-rays.

Genetic testing would be indicated in cases where there is an early onset or multiple family members affected with PD. Testing should be done first on a family member affected with PD. It could include a multigene panel that looks for variants in known PD genes or exome or genome sequencing that looks for any gene variants in the genome that might explain the PD. If a variant in a PD gene is founded, then testing of other family members can be done. If a variant is not found, then this does not rule out a genetic cause.

Treatment and management

There is no cure for PD. Most drugs treat the symptoms of the disease only, although one drug, selegiline (Eldepryl), may slow degeneration of the substantia nigra.

Drugs

The pharmacological treatment of PD is complex. While there are a large number of drugs that can be effective, their effectiveness varies by patient, disease progression, and the length of time the drug has been used. Dose-related side effects may preclude using the most effective dose or require the introduction of a new drug to counteract them. There are five classes of drugs currently used to treat PD.

DRUGS THAT REPLACE DOPAMINE. One drug that helps replace dopamine, levodopa (L-dopa), is the single most effective treatment for the symptoms of PD. L-dopa is a derivative of dopamine and is converted into dopamine by the brain. It may be started when symptoms begin or when they become serious enough to interfere with work or daily living.

L-dopa therapy usually remains effective for five years or longer. Following this, many patients develop motor fluctuations, including peak-dose “dyskinesias” (abnormal movements such as tics, twisting, or restlessness), rapid loss of response after dosing (known as the “on-off” phenomenon), and unpredictable drug response. Higher doses are usually tried, but they may lead to an increase in dyskinesias. In addition, side effects of L-dopa include nausea, vomiting, and low blood pressure upon standing (orthostatic hypotension), which can cause dizziness. These effects usually lessen after several weeks of therapy.

ENZYME INHIBITORS. Dopamine is broken down by several enzyme systems in the brain and elsewhere in the body; blocking these enzymes is a key strategy to prolonging the effect of dopamine. The two most commonly prescribed forms of L-dopa contain a drug to

inhibit the amino acid decarboxylase (an AADC inhibitor), one type of enzyme that breaks down dopamine. These combination drugs are Sinemet (L-dopa plus carbidopa) and Madopar (L-dopa plus benserazide). Controlled-release formulations also aid in prolonging the effective interval of an L-dopa dose.

The enzyme MAO-B inhibitor selegiline may be given as add-on therapy for L-dopa. Research indicates that selegiline may have a neuroprotective effect, sparing nigral cells from damage by free radicals. Because of this and the fact that it has few side effects, it is also frequently prescribed early in the disease before L-dopa is begun. Entacapone and tolcapone, two inhibitors of another enzyme system called catechol-O-methyltransferase (COMT), may reach the market, as early studies suggest that they effectively treat PD symptoms with fewer motor fluctuations and decreased daily L-dopa requirements.

DOPAMINE AGONISTS. Dopamine works by stimulating receptors on the surface of corpus striatum cells. Drugs that also stimulate these cells are called dopamine agonists, or DAs. DAs may be used before L-dopa therapy or added on to avoid requirements for higher L-dopa doses late in the disease. DAs available in the United States include pramipexole (Mirapex), ropinirole (Requip), apomorphine, and bromocriptine (Parlodel). Other dopamine agonists in use outside the United States include cabergoline (Dostinex) and lisuride (Dopergine). The previously used pergolide (Permax) was removed from the market in 2007. Side effects of all the DAs are similar to those of dopamine, plus confusion and hallucinations at higher doses.

ANTICHOLINERGIC DRUGS. Anticholinergics maintain dopamine balance as levels decrease. However, the side effects of anticholinergics (dry mouth, constipation, confusion, and blurred vision) are usually too severe in older patients or in patients with dementia. In addition, anticholinergics rarely work for very long. They are often prescribed for younger patients who have predominant shaking. Trihexyphenidyl (Artane) is the drug most commonly prescribed.

DRUGS WHOSE MODE OF ACTION IS UNCERTAIN. Amantadine (Symmetrel) is sometimes used as an early therapy before L-dopa is begun and as an add-on later in the disease. Its anti-Parkinsonian effects are mild and not seen in many patients. Clozapine (Clozaril) is effective especially against psychiatric symptoms of late PD, including psychosis and hallucinations.

Surgery

Two surgical procedures are used for treatment of PD that cannot be controlled adequately with drug therapy. In PD, a brain structure called the globus pallidus (GPi)

receives excess stimulation from the corpus striatum. In a pallidotomy, the GPi is destroyed by heat delivered by long, thin needles inserted under anesthesia. Electrical stimulation of the GPi is another way to reduce its action. Fine electrodes are inserted to deliver the stimulation, which may be adjusted or turned off as the response dictates. Other regions of the brain may also be stimulated by electrodes inserted elsewhere. In most patients, these procedures lead to significant improvement for some motor symptoms, including peak-dose dyskinesias, which allows the patient to receive more L-dopa, since these dyskinesias are usually what cause an upper limit on the L-dopa dose.

Deep brain stimulation (DBS) can help manage symptoms of PD. It involves surgically implanting a device that delivers electrical stimulation to a part of the brain called the basal ganglia. This treatment can help

Light micrograph of a section through the brain of a patient with Parkinson's disease, showing a neuron (center) containing Lewy bodies (dark red). Lewy bodies, which are deposits of protein, are thought to cause the progressive degeneration of the neurons that leads to the symptoms of this disorder. (Pr. A.M. Vedrenne, CNRI/Science Source)

control motor symptoms like stiffness, slowness, and tremor. It works very well for some people but does not work for all people with PD. It is approved for people who have had PD for at least four years but still have motor problems. DBS is not recommended for people with dementia as it may worsen problems with thinking or memory. Most people can decrease the amount of PD drugs that they need after DBS.

Focused ultrasound can be used to destroy brain cells that cause movement problems in PD patients. The type of symptoms determine the brain cells that are targeted. Focused ultrasound usually immediately decreases symptoms, but the treatment is permanent. The procedure is usually only done on one side of the brain and therefore only affects symptoms on that side, because doing the procedure on both sides may cause speech, swallowing, or memory problems.

Transplant of fetal nigral cells is highly experimental. Its benefits to date have been modest, although improvements in technique and patient selection are likely to change that.

Alternative treatment

Currently, the best treatments for PD involve the use of conventional drugs such as levodopa. Alternative therapies, including acupuncture, massage, and yoga, can help relieve some symptoms of the disease and loosen tight muscles. Alternative practitioners have also applied herbal and dietary therapies, including amino acid supplementation, antioxidant (vitamins A, C, E, selenium, and zinc) therapy, B vitamin supplementation, and calcium and magnesium supplementation, to the treatment of PD. Anyone using these therapies in conjunction with conventional drugs should check with his or her doctor to avoid the possibility of adverse interactions. For example, vitamin B₆, either as a supplement or from foods such as whole grains, bananas, beef, fish, liver, and potatoes, can interfere with the action of L-dopa when the drug is taken without carbidopa.

Exercise, nutrition, and physical therapy

Regular, moderate exercise has been shown to improve motor function without an increase in medication for a person with PD. Exercise helps maintain range of motion in stiff muscles, improve circulation, and stimulate appetite. An exercise program designed by a physical therapist has the best chance of meeting the specific needs of the person with PD. A physical therapist may also suggest strategies for balance compensation and techniques to stimulate movement during slowdowns or freezes.

KEY TERMS

AADC inhibitors—Drugs that block the amino acid decarboxylase, one type of enzyme that breaks down dopamine. Also called DC inhibitors, they include carbidopa and benserazide.

Akinesia—A loss of the ability to move; freezing in place.

Bradykinesia—Extremely slow movement.

COMT inhibitors—Drugs that block catechol-O-methyltransferase, an enzyme that breaks down dopamine. COMT inhibitors include entacapone and tolcapone.

Dopamine—A neurochemical made in the brain that is involved in many brain activities, including movement and emotion.

Dyskinesia—Impairment or difficulty in performing voluntary movements, usually resulting in jerky or interrupted movements.

MAO-B inhibitors—Inhibitors of the enzyme monoamine oxidase B. MAO-B helps break down dopamine; inhibiting it prolongs the action of dopamine in the brain. Selegiline is an MAO-B inhibitor.

Orthostatic hypotension—A sudden decrease in blood pressure upon sitting up or standing. It may be a side effect of several types of drugs.

Substantia nigra—One of the movement control centers of the brain.

Good nutrition is important to maintenance of general health. A person with PD may lose some interest in food, especially if depressed, and may have nausea from the disease or from medications, especially those known as dopamine agonists. Slow movements may make it difficult to eat quickly, and delayed gastric emptying may lead to a feeling of fullness without having eaten much. Increasing fiber in the diet can improve constipation, soft foods can reduce the amount of needed chewing, and a prokinetic drug such as cisapride (Propulsid) can increase the movement of food through the digestive system.

People with PD may need to limit the amount of protein in their diets. The main drug used to treat PD, L-dopa, is an amino acid and is absorbed by the digestive system by the same transporters that pick up other amino acids broken down from proteins in the diet. Limiting protein, under the direction of a physician or a nutritionist, can improve the absorption of L-dopa.

QUESTIONS TO ASK YOUR DOCTOR

- What do scientists know about the causes of Parkinson's disease?
- How does a physician know that a person has Parkinson's disease rather than some other similar medical condition?
- What medications are available for the treatment of Parkinson's disease, and how effective are they?
- Are there herbs or other alternative medicines that can be used for the treatment of Parkinson's disease?

No evidence indicates that vitamin or mineral supplements can have any effect on the disease other than in the improvement of the patient's general health. No antioxidants used to date have shown promise as a treatment except for selegiline, monoamine oxidase B (MAO-B) inhibitor. A large, carefully controlled study demonstrated that vitamin E could not halt disease progression.

Prognosis

Despite medical treatment, the symptoms of PD worsen over time and become less responsive to drug therapy. Late-stage psychiatric symptoms are often the most troubling, including difficulty sleeping, nightmares, intellectual impairment (dementia), hallucinations, and loss of contact with reality (psychosis).

Paroxysmal nocturnal hemoglobinuria

Definition

Paroxysmal nocturnal hemoglobinuria (PNH) is an acquired form of hemolytic anemia that is caused by an intrinsic defect of the cell membrane in red blood cells. Primary PNH is characterized by a deficiency in protective proteins called glycosphosphatidylinositols, and the lack of these proteins allows the innate immune system of the body to attack blood cells and destroy them. Secondary PNH is a bone marrow disorder characterized as aplastic anemia.

As the red blood cells are destroyed, the iron-rich hemoglobin is released and disposed of in the urine,

which can sometimes be red in color. Historically, the acidification of the blood that happens during sleep was thought to contribute to PNH, and this is why “nocturnal” is a component to the disorder’s name; however there is little evidence that sleep has a role in the disease.

Description

Also known as Marchiafava-Micheli syndrome, PNH was first identified in 1882. PNH is caused by a change (mutation) in the gene that encodes phosphatidylinositol glycan A (PIGA), an enzyme that is required for the synthesis of the glycolipid glycosylphosphatidylinositol (GPI). GPI anchors proteins to membranes and when it is missing proteins cannot present on membrane of the cells. Proteins that are anchored to the cell membrane by GPI are important for cell identity, which protects the cell from the body’s immune system. All blood cells develop from hematopoietic stem cells in the bone marrow; when PIGA is mutated in these stem cells, all the cells produced will lack GPI anchors.

Many of the proteins that protect blood cells from the innate immune system require GPI anchors to be expressed on the cell surface. The main proteins involved in this protection are decay-accelerating factor (DAF/CD55) and protectin (CD59/MIRL/MAC-IP), which keep the components of the complement system from binding to the cell membrane. Although all types of blood cells can be susceptible to complement system attack, the RBC are most sensitive to cell lysis. Without GPI anchors, these protective proteins cannot protect blood cells from the complement system.

The severity of PNH varies greatly from individual to individual. In some affected people blood in the urine is barely detectable; others lose so much blood that they require repeated transfusions. In severe cases, abnormal platelets may cause abnormal clotting and about one-third of people with PNH die from clots in the veins of the liver, stomach, or brain.

Genetic profile

PNH is caused by a somatic mutation in the *PIG-A* gene, located on the X chromosome. When this mutation occurs in the bone marrow cells responsible for the production of blood cells, the symptoms of PNH are presented as more defective blood cells outnumber the normal ones that were made prior to the mutation event.

Although females have two X chromosomes, in most cells only one chromosome is actively used for gene transcription while the other is compacted into an inactive form of DNA called heterochromatin. This process is called X-chromosome inactivation. This means that

KEY TERMS

Anemia—A blood condition in which the level of hemoglobin or the number of red blood cells falls below normal values. Common symptoms include paleness, fatigue, and shortness of breath.

Bone marrow—A spongy tissue located in the hollow centers of large bones. Bone marrow is the site of blood cell generation.

Complement system—Part of the innate immune system that helps clear pathogens from an organism. It stimulates a cascade of enzyme activity that effectively lyses cells/pathogens open that are marked for destruction.

Glycosylphosphatidylinositol (GPI)—A molecule that attaches proteins to the membranes of cells.

Hemoglobin—Protein-iron compound in the blood that carries oxygen and carbon dioxide to and from tissues/cells, respectively.

Innate immune system—A population of cells and mechanisms that defends the body against invasive organisms. This protection is generic and not long lasting. The innate immune system is sometimes considered to be the first responder against infection.

Platelets—Small, disc-shaped cells that circulate in the bloodstream and participate in blood clotting.

Red blood cell (RBC)—Hemoglobin-containing blood cells that transport oxygen from the lungs to tissues. In the tissues, the red blood cells exchange their oxygen for carbon dioxide that is then brought back to the lungs.

Somatic mutation—Mutations that occur in only some cells during an individual’s lifetime. These mutations are acquired rather than inherited.

White blood cell (WBC)—A cell in the blood that helps fight infections.

X-chromosome inactivation—The molecular process that inactivates one of two X-chromosomes in most cells present in female mammals. This inactivation prevents females from having twice as many X-chromosome gene products as males of that species.

in most cells, if a somatic mutation occurs on the X-chromosome, the affected gene can have developmental or phenotypic consequences for that cell, tissue, organ, or organism. In this way, women as well as men can suffer from PNH.

Demographics

PNH is a rare disease. In a million people, only about two to six cases of PNH will be diagnosed. PNH can affect any age group but is most common in adults between the ages of 30 and 50. The disease affects both men and women but is slightly more common in women (the ratio is 1.2 to 1). PNH has been described in all ethnicities but may occur in greater numbers in those from Southeast Asia, as this group is more susceptible to aplastic anemia.

Signs and symptoms

Only about one-quarter of people with PNH have the telltale sign, reddish-brown urine, for which the disease is named and is more common in cases of primary PNH. Other symptoms can include those associated with anemia, such as shortness of breath, tiredness, and heart palpitations. More severe cases of PNH can present symptoms like abdominal pain and trouble swallowing, which might be caused by the effect the products of red blood cell damage has on smooth muscle cell function.

Blood clots can also be a serious risk to people with PNH, especially if they travel to the lungs or brain. Forty percent of PNH patients usually develop blood clots at some point in their illness. Clots that form in the major veins of the liver can cause severe pain and damage to the internal organs.

Contributing to anemia in people with PNH is the decreased production of red blood cells in the bone marrow. As the bone marrow fails to produce functioning red blood cells, white blood cells, and platelets, the numbers of these blood cells drop dangerously low and lead to a condition called bone marrow failure. Those affected with PNH may have frequent infections because their white blood cells are decreased in number and the cells that circulate in the blood are abnormal.

Diagnosis

Blood tests can be used in the diagnosis of PNH. The Ham test, developed in 1938, has long been a standard laboratory test for confirming PNH. The test determines whether an individual's red blood cells break down when introduced to a mild acidic environment. Blood cells that are abnormally fragile break down faster in this environment compared to normal cells. The Ham test is not very sensitive or specific to PNH but was historically used for testing blood disorders. A second laboratory test, the sugar water or sucrose lysis test, works on principles similar to the Ham test in that the amount and rate of hemolysis is observed for in a patient's red blood cells when they are placed in low-ionic-strength solution. These tests are

generally considered obsolete now that there are more specific and sensitive diagnostic tools.

The most current laboratory test for PNH is flow cytometry that can measure the levels of CD55 and CD59 in white and red blood cells. In cases of mild and severe PNH the levels of these proteins are very low compared to normal blood cells. Flow cytometry analysis is considered the gold standard for an accurate diagnosis of PNH.

Another marker used in flow cytometry to diagnose PNH is the fluorescein-labeled proaerolysin (FLAER). Proaerolysin is a bacterial protein that selectively binds to GPI proteins. The FLAER test takes advantage of this and uses it as a more accurate marker than CD59 or CD55 in demonstrating a deficit in GPI in cases of PNH.

Individuals who are young with unexplained thrombosis (blood clotting) and have thrombosis in an unusual site (e.g., intra-abdominal veins, cerebral veins, dermal veins), have any evidence of hemolysis (i.e. a raised LDH), or have a low red blood cell, white blood cell, or platelet counts should be screened for PNH. Those who have a diagnosis of aplastic anemia should also be screened annually.

Treatment and management

Treatment can depend on the severity of the case of PNH. For mild forms of PNH patients may only have to take supplements of folic acid and iron to increase red blood cell production. In more severe cases steroids may be used to slow down the destruction of blood cells and symptoms of anemia. Patients who suffer from thrombosis can take anticoagulants to prevent the occurrence of blood clots. Blood transfusions may also be used for the treatment of PNH to replace abnormal blood cells with functional cells.

Bone marrow transplants are perhaps the only way to cure PNH. Bone marrow from a close relative such as a sibling can be used to replace the defective marrow of a PNH patient. The procedure is quite risky, with a 15%–20% chance of death, and is available only in the most severe cases of PNH or when other treatments have failed to improve a patient's symptoms.

Prognosis

After an affected individual has been diagnosed with PNH they usually live for another 10 to 20 years. About 25% of people with PNH live more than 25 years after first being diagnosed. In a few people (about 15%), the disease disappears altogether and the person recovers spontaneously.

QUESTIONS TO ASK YOUR DOCTOR

- What treatments are suggested for my type of PNH?
- I have a mild form of PNH; is it possible for it to progress to a more severe form of the disease?
- What physical and mental characteristics are most commonly associated with paroxysmal nocturnal hemoglobinuria?
- What is the genetic basis for this disorder, and how likely is it that my children will inherit the disease from me?
- Are there support groups or organization that can provide additional information about this condition?

Most people who die from PNH do so because of abnormal clotting. About 10% of these individuals develop and eventually die from another disease involving red blood cells, aplastic anemia. About 5% of people with PNH develop a disease involving abnormal white blood cells, acute myelogenous leukemia.

Patent ductus arteriosus

Definition

Patent ductus arteriosus (PDA) is a heart abnormality that occurs when the ductus arteriosus (the temporary fetal blood vessel that connects the aorta and the pulmonary artery) does not close at birth.

Description

The ductus arteriosus is a temporary fetal blood vessel that connects the aorta and the pulmonary artery before birth. The ductus arteriosus should be present and open before birth while the fetus is developing in the uterus. Since oxygen and nutrients are received from the placenta and the umbilical cord instead of the lungs, the ductus arteriosus acts as a "short cut" that allows blood to bypass the deflated lungs and go straight out to the body. After birth, when the lungs are needed to add oxygen to the blood, the ductus arteriosus normally closes. The closure of the ductus arteriosus ensures that blood goes to the lungs to pick up oxygen before going out to the body. Closure of the ductus arteriosus usually occurs at birth as levels of certain chemicals, called prostaglandins, change and the lungs fill with air. If the ductus arteriosus closes correctly, the blood pumped from the heart goes to the lungs, back into the heart, and then out to the body through the aorta. The blood returning from the lungs and moving out of the aorta carries oxygen to the cells of the body.

In some infants, the ductus arteriosus remains open (or patent), and the resulting heart defect is known as patent ductus arteriosus (PDA). In most cases, a small PDA does not result in physical symptoms. If the PDA is larger, health complications may occur.

In an average individual's body, the power of blood being pumped by the heart and other forces leads to a certain level of pressure between the heart and lungs. The

Failure of the temporary fetal blood vessel that connects the aorta and the pulmonary artery (ductus arteriosus) to close after birth results in patent ductus arteriosus. This open duct interferes with proper blood flow through the aorta. (Gale)

pressure between the heart and lungs of an individual affected by PDA causes some of the oxygenated blood that should go out to the body (through the aorta) to return back through the PDA into the pulmonary artery. The pulmonary artery takes the blood immediately back to the lungs. The recycling of the already oxygenated blood forces the heart to work harder as it tries to supply enough oxygenated blood to the body. In this case, the left side of the heart usually grows larger as it works harder and must contain all of the extra blood moving back into the heart. This is known as a left-to-right or aortic-pulmonary shunt.

The size of the PDA determines how much harder the heart has to work and how much bigger the heart becomes. If the PDA is large, the bottom-left side of the heart is forced to pump twice as much blood because it must supply enough blood to recycle back to the lungs and move out to the body. As the heart responds to the increased demands for more oxygenated blood by pumping harder, the pulmonary artery has to

change in size and shape in order to adapt to the increased amount and force of the blood. In some cases, the increase in size and shape changes the pressure in the pulmonary artery and lungs. If the pressure in the lungs is higher than that of the heart and body, blood returning to the heart will take the shortcut back into the aorta from the pulmonary artery through the PDA instead of going to the lungs. This backward flowing of blood does not carry much oxygen. If blood without much oxygen is being delivered to the body, the legs and toes turn blue or cyanotic. This is called a shunt reversal.

When a PDA results in a large amount of blood being cycled in the wrong order, either through a left-to-right shunt or shunt reversal, the overworked, enlarged heart may stop working (congestive heart failure) and the lungs can become filled with too much fluid (pulmonary edema). At this time, there is also an increased risk for a bacterial infection that can inflame the lining of the heart (endocarditis). These three complications are very serious.

Genetic profile

PDA can be a result of an environmental exposure before birth, inheriting a specific changed or mutated gene or genes, a symptom of a genetic syndrome, or be caused by a combination of genetic and environmental factors (multifactorial). Recent studies in mice and supporting human genomic data have shown that a critical region in chromosome 2 encoding eight genes, including genes for bone morphogenetic protein (BMP) 9 and BMP10, may be involved in PDA. These proteins are critical for the remodeling of newly formed microvascular beds.

Environmental exposures that can increase the chance for a baby to be affected by PDA include fetal exposure to rubella before birth, preterm delivery, and birth at a high-altitude location.

PDA can be an inherited condition running in families as isolated PDA or part of a genetic syndrome. In either case, there are specific gene changes or mutations that lead to an abnormality in the elastic tissue forming the walls of the ductus arteriosus. The genes causing isolated PDA have not been identified, but it is known that PDA can be inherited through a family in an autosomal dominant pattern or an autosomal recessive pattern.

Every person has approximately 30,000 genes, which tell our bodies how to grow and develop correctly. Each gene is present in pairs since one is inherited from the mother, and one is inherited from the father. In an autosomal dominant condition, only one changed or mutated copy of the gene for PDA is necessary for a person to have PDA. If a parent has an autosomal dominant form of PDA, there is a 50% chance for each child to have the same or similar condition.

PDA can also be inherited in an autosomal recessive manner. A recessive condition occurs when a child receives two changed or mutated copies of the gene for a particular condition, such as PDA (one copy from each parent). Individuals with a single changed or mutated copy of a gene for a recessive condition are known as carriers and have no health problems related to the condition. In fact, each individual carries between five and 10 genes for harmful, recessive conditions. However, when two people who each carry a changed or mutated copy of the same gene for a recessive condition meet, there is a chance, with each pregnancy, for the child to inherit the two changed or mutated copies from each parent. In this case, the child would have PDA. For two known carriers, there is a 25% risk with each child to have a child with PDA, a 50% chance to have a child who is a carrier, and a 25% chance to have a child who is neither affected nor a carrier.

KEY TERMS

Aorta—The main artery located above the heart that pumps oxygenated blood out into the body. Many congenital heart defects affect the aorta.

Catheterization—The process of inserting a hollow tube into a body cavity or blood vessel.

Ductus arteriosus—The temporary channel or blood vessel between the aorta and pulmonary artery in the fetus.

Echocardiograph—A record of the internal structures of the heart obtained from beams of ultrasonic waves directed through the wall of the chest.

Electrocardiogram (ECG, EKG)—A test used to measure electrical impulses coming from the heart in order to gain information about its structure or function.

Endocarditis—A dangerous infection of the heart valves caused by certain bacteria.

Oxygenated blood—Blood carrying oxygen through the body.

Pulmonary artery—An artery that carries blood from the heart to the lungs.

Pulmonary edema—A problem caused when fluid backs up into the veins of the lungs. Increased pressure in these veins forces fluid out of the vein and into the air spaces (alveoli). This interferes with the exchange of oxygen and carbon dioxide in the alveoli.

Most cases of PDA occur as the result of multifactorial inheritance, which is caused by the combination of genetic factors and environmental factors. The combined factors lead to isolated defects in the elastic tissue forming the walls of the ductus arteriosus. Family studies can provide different recurrence risks depending on the family member affected by multifactorial PDA. If an individual is affected by isolated, multifactorial PDA, they have a 2%–4% chance of having a child affected by PDA. If a couple has one child with isolated, multifactorial PDA, there is a 3% chance that another of their children could be affected by PDA. If a couple has two children affected by isolated, multifactorial PDA, there is a 10%–25% chance that they could have another child affected by PDA.

Unless a specific pattern of inheritance, preterm delivery, or known exposure is found through the examination of a detailed pregnancy and family history, the multifactorial family studies are used to estimate the possible risk of recurrence of PDA in a family.

Demographics

PDA is a very common heart disorder. The incidence of isolated PDA at live-term birth is 1 per 2,000. This accounts for 5%–10% of all congenital heart defects. PDA can occur in full-term infants, but is seen most frequently in preterm infants, infants born at a high altitude, and babies whose mothers were affected by German measles (rubella) during pregnancy. PDA is two to three times more common in females than in males. PDA occurs in individuals of every ethnic origin and does not occur more frequently in any one country or ethnic population.

Signs and symptoms

The main sign of PDA is a constant heart murmur that sounds like the hum of a refrigerator or other machinery. This murmur is usually heard by the doctor using a stethoscope. Otherwise, there are no specific symptoms of PDA, unless the ductus arteriosus size is large. Children and adults with a large ductus arteriosus can show difficulty in breathing during moderate physical exercise, an enlarged heart, and failure to gain weight. In some cases, heart failure and pulmonary congestion can indicate a PDA.

Diagnosis

Diagnosis is most often made by detecting the characteristic “machinery” heart murmur heard by a doctor through a stethoscope. Tests such as a chest x-ray, echocardiograph, and ECG are used to support the initial diagnosis. Other indications of PDA include failure to gain weight, frequent chest infections, heavy breathing during mild physical exertion, congestive heart failure, and pulmonary edema. Prenatal ultrasounds are unable to detect PDA because the heart defect does not occur until the time of birth.

Treatment and management

The treatment and management of PDA depends upon the size of the PDA and symptoms being experienced by the affected individual. In some cases, a PDA can correct itself in the first months of life. In preterm infants experiencing extreme symptoms, the first step in correcting a PDA is through treatment with Prostaglandin E1 until such time that the infant could survive corrective surgery. In less severe cases, treatment with medicine such as enteral paracetamol or intravenous Indomethacin is indicated. In preterm infants in which PDA is not closed through medication, full-term infants affected by PDA, and adults, surgery is an option for closing the ductus arteriosus. In 2000 and 2001, researchers developed and reviewed alternatives to surgical closure such as interventional cardiac catheterization and video-assisted

QUESTIONS TO ASK YOUR DOCTOR

- What is the “ductus arteriosus,” and what function does it have in the body?
- Why is patent ductus arteriosus classified as a genetic disease?
- How is patent ductus arteriosus diagnosed in a child?
- What treatments are available for this disorder?

thoroscopic surgical repair. A cardiologist can help individuals determine the best method for treatment based on their physical symptoms and medical history.

Prognosis

Adults and children can survive with a small opening remaining in the ductus arteriosus. Treatment, including surgery, of a larger PDA is usually successful and frequently occurs without complications. Proper treatment allows children and adults to lead normal lives.

Pedigree analysis

Definition

A pedigree is a family tree or chart made of symbols and lines that represent a patient's genetic family history. The pedigree is a visual tool for documenting biological relationships in families and the presence of diseases. Pedigree analysis is an assessment made by a medical professional about genetic risk in a family.

Purpose

Pedigrees are most often constructed by medical geneticists or genetic counselors. People are referred to genetic professionals because of concern about the presence of a genetic condition in a family member. Pedigree analysis can help identify a genetic condition running through a family, aids in making a diagnosis, and aids in determining who in the family is at risk for genetic conditions. During pedigree construction, the family's beliefs about the cause for a genetic disease or emotional issues related to a diagnosis may be revealed. For instance, family members may experience guilt or shame about passing on a genetic trait. Thus, the communication process involved in taking the family history may allow the health care provider to identify areas in which the patient may need reassurance, education, or emotional support.

Creating a pedigree

Pedigree symbols

A standard set of symbols has been established for use in creating pedigrees. Some of the most commonly used symbols are shown in this entry. When a person is affected with a birth disorder, intellectual disability, or other health problems, the individual is shaded or marked. If more than one condition is present in a family, different identifying marks should be made. A key to decipher these

markings should also be included on the pedigree. The meaning of each horizontal and vertical line is also shown.

Information obtained

A typical pedigree is made of information about three generations of a family. The consultand is the person seeking genetic evaluation, counseling, or testing. The proband in a family is the person in a family affected with a genetic disease. Beginning with the consultand, questions should be asked about the health of first-, second-, and third-degree relatives. First-degree relatives are children, parents, and siblings. Second-degree relatives are half-siblings, nieces, nephews, aunts and uncles, grandparents, and grandchildren. Third-degree relatives are first cousins. Important information to obtain on both sides of the family includes:

- ages or dates of birth
- presence of any birth disorders, learning problems, chronic illnesses, surgeries, or medical treatments
- presence of specific features of a disease if the condition is suspected in the family
- genetic testing results if previously performed in the family
- cause of death for deceased family members
- pregnancy losses, stillbirths, or infant deaths and causes
- infertility in the family
- ethnic background of the families
- consanguinity

It is important to establish the accuracy of information given by patients. Therefore, medical records are often requested in order to provide accurate risk assessment.

Pedigree patterns

Autosomal dominant inheritance

Pedigree 1 illustrates the occurrence of an autosomal dominant disorder called neurofibromatosis (NF). NF is characterized by growths under the skin called neurofibromas, dark spots on the skin called café au lait spots, and an eye finding called Lisch nodules. NF is caused by a single dominant gene on chromosome 17. Each person who is affected with NF has a 50% chance to pass the gene on to each child. The symptoms of NF are variable so that some family members are affected more seriously than others. The pedigree shows that in autosomal dominant inheritance, multiple generations of a family are affected. This is called vertical transmission of a trait through a family. Males and females are equally likely to be affected. In a particular sibship, about half of the siblings are affected.

Pedigree Symbols

-  Male
-  Female
-  Gender unknown
-  Miscarriage
-  Elective terminated of Pregnancy
-  Affected female
-  Affected male
-  Carrier female
-  Carrier male
-  Deceased

Pedigree 1: Neurofibromatosis
 Autosomal Dominant Inheritance

Pedigree 2: Cystic Fibrosis
 Autosomal Recessive Inheritance

Pedigree 3: Hemophilia
 X-Linked Recessive Inheritance

The illustration above identifies several common symbols used to represent individuals in a pedigree chart. The three pedigree charts on the right provide examples of different types of inheritance patterns and the transmission of abnormal genes through three generations in a family. (Gale)

Autosomal recessive inheritance

Pedigree 2 illustrates the occurrence of an autosomal recessive disorder called cystic fibrosis (CF) in a family. CF is a chronic respiratory disease characterized by digestive problems and a shortened lifespan. A person with CF has two genes for the condition on chromosome 7. Each parent is an obligate carrier of a gene for the condition. When both parents are carriers, there is a one in four or 25% chance that each child they have together will be affected. In autosomal recessive inheritance, siblings are most often affected rather than people in successive generations. Since siblings are affected, this is called horizontal transmission of a disease in the family. Males and females are equally likely to be affected in this type of inheritance, and others in the family have an increased chance to be unaffected carriers of the disease.

X-linked recessive inheritance

Pedigree 3 illustrates the occurrence of an X-linked disorder called hemophilia. Hemophilia is characterized by excessive bleeding and bruising. Depending on the type of hemophilia, a particular blood-clotting factor is deficient. In X-linked recessive inheritance, males are affected with the condition while females are unaffected carriers. In X-linked recessive inheritance, vertical transmission of the disease is seen, with skipping of generations. There is no male-to-male transmission of a disease in this type of inheritance. This is because males pass their Y chromosome to each son, instead of the X chromosome with the disease gene. Each daughter of an affected male is an obligate carrier of the disease, since she will always inherit his X chromosome. There is a 50% chance that each son of a carrier woman will be affected. There is a 50% chance that each daughter of a carrier female will be a carrier.

Pelizaeus-Merzbacher disease

Definition

Pelizaeus-Merzbacher disease (PMD) is an X-linked recessive neurological condition that is associated with abnormalities in myelin, the insulation surrounding the nerves in the brain and spinal cord. It is associated with poor muscle control, involuntary repetitive movements of the eyes (nystagmus), floppy muscles (hypotonia), problems with controlling movement, stiff movements of the legs, developmental delays, and progressive deterioration of intellectual function. It primarily affects males.

Description

PMD was named for two German doctors, F. Pelizaeus and L. Merzbacher, who first described the condition in the late 1800s. The severity of characteristics in PMD can range from mild to severe. PMD primarily affects males, but occasionally females have mild or moderate symptoms. PMD is also called a leukodystrophy, meaning that it affects the myelin, sometimes called the white matter, in the brain and spinal cord. The brain and the spinal cord together are called the central nervous system.

Genetic profile

PMD is caused by a pathogenic variant (mutation) in the proteolipid protein gene (*PLP*). The *PLP* gene has the instructions to make proteolipid protein, one of the proteins that make up myelin in the central nervous system. When there is a pathogenic variant in the *PLP* gene, the myelin is not formed properly or is not made at all, resulting in PMD.

Genes are organized on structures called chromosomes. There are hundreds to thousands of genes on each chromosome. There are 46 chromosomes in each cell of the body. They are grouped into 23 pairs. The first 22 pairs are the same in both males and females. The 23rd pair are called the sex chromosomes; having one X chromosome and one Y chromosome causes a person to be male; having two X chromosomes causes a person to be female. A fetus acquires one member of each pair from

the mother's egg and one member from the father's sperm.

The *PLP* gene is located on the X chromosome. Since males have only one X chromosome, they have only one copy of the *PLP* gene. Thus, a male with a variant in his *PLP* gene will have PMD. Females have two X chromosomes and, therefore, have two copies of the *PLP* gene. If they have a variant in one copy of their *PLP* genes, they may only have mild symptoms of PMD or no symptoms at all, because their normal copy of the *PLP* gene makes normal myelin. Females who have one copy of the *PLP* gene with a variant and one normal copy are called carriers.

Inheritance

PMD is passed on through families by X-linked recessive inheritance, which means that affected males are related through females in the family. A male does not pass PMD on to his sons. Females pass one of their X chromosomes on to their sons or daughters. If the normal X chromosome is passed on, her son or daughter will be unaffected and cannot pass PMD onto their children. However, if the X chromosome with the *PLP* variant is passed on, a daughter will be a carrier, while the son will have PMD. Therefore, a female *PLP* variant carrier has a 50%, or one in two, chance of having a normal child (son or daughter), a 25%, or one in four, chance of having a carrier daughter, and a 25%, or one in four, chance of having an affected son. Males with PMD usually do not reproduce and therefore do not pass PMD on. Males with a milder form of PMD called SPG2 can reproduce, and all of their daughters are carriers of the *PLP* gene variant, and none of their sons inherit it. There have been some rare cases where the *PLP* variant was *de novo*, meaning that it originated in the person affected with PMD and was not inherited.

Pathogenic Variants

Different types of pathogenic variants in the *PLP* gene cause PMD. Everyone in a single family who has the condition, or is a carrier, has exactly the same *PLP* variant. The most common type of variant is a duplication (doubling) of the *PLP* gene, which means that two copies of the *PLP* gene are present on one X chromosome. Having this extra copy causes the myelin to be abnormal and leads to PMD. About 50%–75% of people with PMD have a *PLP* duplication. The duplication usually causes a severe form of PMD. Another 15% to 20% of people with PMD have point variants within their *PLP* gene. A point variant is like a typo in the gene. It changes the message of the gene and also causes the myelin to be abnormal. A few patients with PMD have a deletion of the *PLP* gene, which means that they have no copies of the *PLP* gene if they are male, or one copy if they are a carrier female. Another 5%

to 20% of patients have characteristics of PMD, but no variant has been found in their *PLP* gene. It is possible that they have an unknown variant in the *PLP* gene or a variant in another gene.

Some people with symptoms of PMD who do not have a variant in the *PLP* gene may have what is called Pelizaeus-Merzbacher-like disease. This condition has similar symptoms to PLP but is autosomal recessive. An autosomal recessive condition results when someone has variants in both copies of a gene that is found on a chromosome other than the sex chromosomes. Two carriers of Pelizaeus-Merzbacher-like disease have a 25% chance of having a child with the condition. People with Pelizaeus-Merzbacher-like disease can have variants in the *GJC2* or the *NPC1* gene. It is possible that variants in other genes cause this condition.

Demographics

PMD has been described in people from all over the world and from many different ethnic backgrounds. The condition affects males far more frequently than females, with an estimated one in 200,000 to 500,000 males affected in the United States.

Signs and symptoms

There is a range in the severity of symptoms of PMD. Rough categories have been set up based on the age of onset and severity of symptoms. However, many patients do not fall neatly into one of these categories and instead fall somewhere in between. Patients with different severities have been seen in the same family.

In the most severe form of PMD, symptoms are first noticed shortly after birth or in infancy. This is called *connatal* PMD. One of the first signs usually noticed is *nystagmus*, a side-to-side jerking of the eyes. This symptom does not usually cause problems with vision. Patients can have significant intellectual disability and never learn to walk, talk, or care for themselves. They may have noisy breathing called *stridor* and difficulty sucking. Seizures may be present in these children. They often are small for their age and have trouble gaining weight. Early on, they have floppy muscles called *hypotonia*, but later develop *spasticity*, which is stiffness or tightness in the muscles and joints.

Those patients who have classical PMD, which is less severe than the *connatal* type, usually have *nystagmus*, which develops within the first few months of life. Other symptoms typically develop within the first few years. These children also have *hypotonia* that turns into *spasticity*. Sometimes these patients will learn to walk. However, they may need a wheelchair as their *spasticity* increases. Shaking of the head and neck, called *titubation*,

KEY TERMS

Central nervous system (CNS)—In humans, the central nervous system is composed of the brain, the cranial nerves, and the spinal cord. It is responsible for the coordination and control of all body activities.

Leukodystrophy—A disease that affects the white matter, called myelin, in the CNS.

Myelin—An insulation that is wrapped around the nerves in the body. In the central nervous system, it is also called the white matter.

Nystagmus—Involuntary, rhythmic movement of the eye.

Proteolipid protein gene (PLP)—A gene that makes a protein that is part of the myelin in the central nervous system. Variants in this gene cause PMD.

Spasticity—Increased muscle tone, or stiffness, which leads to uncontrolled, awkward movements.

may occur. Although these children often have moderate intellectual disability, they often learn to talk and often understand more than is evident by their speech.

A less severe type of PMD is called the PLP null syndrome. Those who are affected do not usually have nystagmus, and their spasticity may be mild. Symptoms develop in early childhood. This group of patients may also have a peripheral neuropathy, which is a problem with the nerves that run from the spinal cord through the body. It can cause weakness and problems with sensation such as difficulties sensing whether something is hot or cold. These patients usually talk and walk. They may have mild to moderate intellectual disability.

There are some people who have *PLP* variants who are very mildly affected. They have spasticity and sometimes have other problems such as a frequent and sudden urge to urinate that may be difficult to control (spastic bladder). Intelligence is normal or mildly impaired. This mild form of PMD is also called spastic paraplegia 2 (SPG2).

Diagnosis

When problems are first noticed in an infant or a child, they will usually be referred to a pediatric neurologist who is specially trained in diseases of the nerves and muscles in children. At the initial evaluation, the neurologist will perform a clinical examination to evaluate the child's development and how well the nerves and muscles work. At that time, a thorough family history should

be taken to determine whether there are others in the family that are affected and, if so, how they are related.

One of the initial tests that may be ordered is magnetic resonance imaging (MRI). In this test, pictures of the brain are taken, and the amount of white matter (myelin) in the brain is measured. In people with PMD, the amount of white matter is usually significantly reduced, compared to normal. However, a decrease in white matter is seen in other neurological conditions and is not specific to PMD. An MRI can be helpful in diagnosing PMD, but if changes are seen on MRI, it does not confirm the diagnosis of PMD. Changes in the white matter may only be seen after one to two years of age, when the brain has matured.

If no one else in the family is known to be affected, testing may be performed to rule out conditions other than PMD. Often, PMD will not be initially suspected when no one else is affected in the family. It is not uncommon for people to be misdiagnosed initially. Sometimes, the diagnosis of PMD is made only after a second affected child is born into a family.

Genetic testing

Genetic testing is the only way to definitely diagnose someone with PMD. If PMD is suspected, then variants can be looked for in just the *PLP* gene or in a number of genes, including the *PLP* gene. If testing is only done on the *PLP* gene, then the gene is often first evaluated for deletions or duplications of the gene. If this test is negative, additional testing can be done to look for other variants in the gene. In 80% of people who have clear symptoms of PMD, a variant can be found in the *PLP* gene. If a variant in the *PLP* gene has been identified, then testing is recommended in family members who might be carriers or affected with PMD.

Prenatal testing

Testing during pregnancy to determine whether an unborn child is affected is possible if genetic testing in a family has identified a specific *PLP* variant. This can be done at 10 to 12 weeks of gestation by a procedure called chorionic villus sampling (CVS), which involves removing a tiny piece of the placenta and examining the cells. It can also be done by amniocentesis after 16 weeks of gestation by removing a small amount of the amniotic fluid surrounding the baby and analyzing the cells in the fluid. Each of these procedures has a small risk of miscarriage associated with it. Couples who are interested in these options should have genetic counseling to carefully explore all of the benefits and limitations of these procedures.

Treatment and management

There is no treatment or cure for PMD. Medical management is aimed at making life as full as possible and keeping people free from illness. Different types of therapy might be suggested. An occupational therapist can suggest adaptive devices to make it easier for an affected person to get around his or her home and perform everyday activities such as eating and using the bathroom. For example, they may suggest installing bars to use in the bathroom or shower or special utensils for eating. Physical therapy can be helpful for reducing spasticity. Some patients with PMD require a feeding tube to help take in more calories. There are also medications that can assist in treating spasticity and seizures.

Treatments Under Investigation

Treatments for people who have duplications of the *PLP* gene or who have variants that increase the production of PLP protein are under investigation. Pharmacologic agents that lower expression of PLP1 are being researched. Researchers are also investigating the use of synthetic mRNA to decrease the production of the PLP protein. mRNA is created from DNA and contains the instructions for the production of proteins. Decreasing the production of the PLP protein seems to regenerate myelin and reduce the symptoms of PMD in mice. This therapy needs to be tested in human patients.

Research is also being done on a drug that may help treat PMD in some people. Researchers have found that cells from a mouse with PMD appeared to be damaged by excess iron. They injected a drug into the mice with PMD that binds to and removes iron. This drug appeared to stimulate the formation of new myelin. They plan to test this in children in Europe.

Prognosis

The prognosis for patients with PMD varies in part due to the severity of the symptoms. The quality of care that patients receive also makes a difference in their quality of life. Boys with congenital PMD may die in infancy or early childhood, although some have survived into their 30s. Those with classic PMD or the PLP null syndrome usually reach adulthood, and some have survived into their 70s. Males with SPG2 usually have a normal lifespan. The symptoms of PMD usually progress very slowly, and some people have a plateau of their symptoms over time. Some people's condition may seem to worsen over time, but that is likely to be due to factors such as growth spurts, poor nutrition, or frequent illness and not progression of the disease. Most patients with PMD die from pulmonary or breathing difficulties.

QUESTIONS TO ASK YOUR DOCTOR

- What are the usual signs and symptoms associated with Pelizaeus-Merzbacher disease?
- What is known about the genetic basis of this disorder?
- At what age can Pelizaeus-Merzbacher disease be diagnosed, and how is that diagnosis made?
- What factors affect the prognosis for a child diagnosed with Pelizaeus-Merzbacher disease?

Pendred syndrome

Definition

Pendred syndrome is an inherited condition that causes hearing loss typically beginning at birth and usually leads to the development of an enlarged thyroid, called a goiter. The thyroid is a gland responsible for normal body growth and metabolism. People with Pendred syndrome often have altered development of certain bones in the inner ear and/or balance problems. Vaughan Pendred first described the presence of hearing loss and goiter in two sisters in 1896, and the condition became known as Pendred syndrome. Genetic research has identified a gene on chromosome 7 that is usually altered in people with Pendred syndrome.

Description

Pendred syndrome is sometimes called goiter-sensorineural deafness, due to the common existence of both goiter and a form of hearing loss called sensorineural hearing loss in affected individuals. In order to understand how goiter occurs, it is helpful to first understand how the thyroid gland normally works. The thyroid is located underneath the larynx (voice box), in the front of the neck. The main role of the thyroid is to trap iodine, an essential nutrient found in various foods as well as salt, and to use it to make two important hormones: T3 and T4. These thyroid hormones allow the body to grow normally and to increase the speed of metabolism (breakdown) of nutrients. The thyroid is able to create these hormones because of a series of chemical reactions. A portion of the brain called the hypothalamus is responsible for controlling many body functions. One of its functions is to make a chemical called thyroid-releasing hormone (TRH). This hormone travels to another gland, called the anterior pituitary gland, which is located underneath the brain. The TRH stimulates the anterior pituitary gland, which makes a chemical called thyroid-stimulating hormone (TSH). This hormone travels to the thyroid and activates the release of T3 and T4 into the body.

The word “goiter” is used to describe an enlargement of the thyroid gland. People with goiter may have hypothyroidism (they make too little T3/T4), hyperthyroidism (they make too much T3/T4), or they may have thyroid glands that work normally. Approximately 44%–50% of people with Pendred syndrome have hypothyroidism, while the remaining 50%–56% have thyroid glands that create a normal amount of thyroid hormones. However, approximately 75% develop goiter at some point in time, although it is rarely present at birth. Thirty to 40% of individuals develop an enlarged thyroid in late childhood or during their early teenage years. The remaining 60%–70% show symptoms during their early adult years. The enlargement of the thyroid gland happens because the mechanisms that control iodine transfer within the cells of the thyroid do not work well. This transfer is necessary to allow the iodine to bind to (and in doing so, help generate) thyroid hormones stored inside the thyroid. Since the iodine is not moved to the correct area of the thyroid, it becomes “pooled,” rather than attaching itself to thyroid hormones. This faulty processing of iodine among people with Pendred syndrome can often be confirmed by the use of a perchlorate discharge test. Perchlorate is a chemical that causes the pooled iodine to be pushed out of the thyroid into the bloodstream, where it can be measured. Since people with Pendred syndrome usually have more pooled iodine than normal, they will push out or discharge a larger amount of iodine when they are exposed to perchlorate. However, not all affected individuals show abnormal results, so the test is not perfect.

Pendred syndrome causes a specific type of hearing impairment called sensorineural hearing loss (SNHL). The ear can be divided into three main parts: the outer ear, the middle ear, and the inner ear. The parts of the outer ear include the pinna (the visible portion of the ear), the ear canal, and the eardrum. The pinna directs sound waves from the environment through the ear canal, toward the eardrum. The eardrum vibrates and causes tiny bones (called ossicles), which are located in the middle ear, to move. This movement causes pressure changes in fluids surrounding the parts that make up the inner ear.

The main structures of the inner ear are the cochlea and the vestibular system. These structures send information regarding hearing and balance to the brain. The cochlea is shaped like a snail shell, and it contains specialized sensory cells (called hair cells) that change the sound waves into electrical messages. These messages are then sent to the brain through a nerve (called the auditory nerve) that allows the brain to “hear” sounds from the environment. The vestibular system is a specialized organ that helps people maintain balance. The vestibular system contains three structures called semicircular canals, which send electrical messages to the brain about

KEY TERMS

Cochlea—A bony structure shaped like a snail shell located in the inner ear. It is responsible for changing sound waves from the environment into electrical messages that the brain can understand, so people can hear.

Cochlear implantation—A surgical procedure in which a small electronic device is placed under the skin behind the ear and is attached to a wire that stimulates the inner ear, allowing people who have hearing loss to hear useful sounds.

Enlarged vestibular aqueduct (EVA)—An enlargement of a structure inside the inner ear called the vestibular aqueduct, which is a narrow canal that allows fluid to move within the inner ear. EVA is seen in approximately 10% of people who have sensorineural hearing loss.

Goiter—An enlargement of the thyroid gland, causing tissue swelling that may be seen and/or felt in the front of the neck. It may occur in people who have overactive production of thyroid hormones (hyperthyroidism), decreased production of thyroid hormones (hypothyroidism), or normal production of thyroid hormones.

Metabolism—The total combination of all of the chemical processes that occur within cells and tissues of a living body.

Pendrin—A protein encoded by the *SLC26A4* gene located on chromosome 7q31. Pendrin protein is

believed to transport iodide and chloride within the thyroid and the inner ear.

Perchlorate discharge test—A test used to check for Pendred syndrome by measuring the amount of iodine stored inside the thyroid gland. Individuals with Pendred syndrome usually have more iodine stored than normal, and thus their thyroid will release a large amount of iodine into the bloodstream when they are exposed to a chemical called perchlorate.

Sensorineural hearing loss (SNHL)—Hearing loss that occurs when parts of the inner ear, such as the cochlea and/or auditory nerve, do not work correctly. It is often defined as mild, moderate, severe, or profound, depending upon how much sound can be heard by the affected individual.

Thyroid gland—A gland located in the front of the neck that is responsible for normal body growth and metabolism. The thyroid traps a nutrient called iodine and uses it to make thyroid hormones, which allow for the breakdown of nutrients needed for growth, development, and body maintenance.

Vestibular system—A complex organ located inside the inner ear that sends messages to the brain about movement and body position. It allows people to maintain their balance when moving by sensing changes in their direction and speed.

movement and body position. This allows people to maintain their balance when moving by sensing changes in their direction and speed.

Sensorineural hearing loss occurs when parts of the inner ear (including the cochlea and/or auditory nerve) do not work correctly. The amount (or degree) of hearing loss can be described by measuring the hearing threshold (the sound level that a person can just barely hear) in decibels (dB). The greater a person's dB hearing level, the louder the sound must be to just barely be heard.

Hearing loss is often defined as mild, moderate, severe, or profound. For people with mild hearing loss (26–45 dB), understanding conversations in a noisy environment, at a distance, or with a soft-spoken person is difficult. Moderate hearing loss (46–65 dB) causes people to have difficulty understanding conversations, even if the environment is quiet. People with severe hearing loss (66–85 dB) have difficulty hearing conversation unless

the speaker is standing nearby or is talking loudly. Profound hearing loss (85 dB) may prevent people from hearing sounds from their environment or even loud conversation. People with Pendred syndrome generally have severe to profound SNHL that is congenital (i.e., present at birth) in both ears. However, some affected individuals develop SNHL during childhood, after they have learned to speak.

People with SNHL often undergo specialized imaging tests, such as computed tomography (CT) and/or magnetic resonance imaging (MRI) scans, which create detailed images of the tissue and bone structures of the inner ear. Approximately 85% of people affected with Pendred syndrome have physical changes in the inner ear that can be seen with these tests. A common finding is a visible change in the snail-shaped cochlea called a Mondini malformation, in which the cochlea is underdeveloped and has too few coils compared to a normal cochlea. Another visible change sometimes seen in the

inner ear is called enlarged vestibular aqueduct. The vestibular aqueduct is a narrow canal that allows fluid to move within the inner ear. Enlarged vestibular aqueduct (EVA) is the most common form of inner ear abnormality that is seen with CT or MRI scans. As the name implies, the vestibular aqueduct (canal) is larger than normal in people with EVA. Although EVA is seen in approximately 10%–12% of people who are born with SNHL, some people with EVA can have SNHL that fluctuates (comes and goes) or is progressive (gradually worsening), as well as balance problems.

In spite of the fact that Pendred syndrome has typically been diagnosed among people with both SNHL and goiter/thyroid problems, research supports the finding that some people with EVA and SNHL have a form of Pendred syndrome, even if they do not have goiter or thyroid problems.

Pendred syndrome causes vestibular dysfunction in approximately 66% of affected individuals, which means they have abnormalities in their vestibular (balance) system. This may cause problems such as dizziness because they cannot sense changes in direction or speed when they are moving.

A closely related condition involving hearing loss is DFNB4 hearing loss. This type of hearing loss is considered a nonsyndromic hearing loss because there are generally no other related abnormalities in the individual. It is very difficult to differentiate this type of hearing loss from Pendred syndrome. Researchers have discovered that DFNB4 hearing loss is caused by mutations in the same gene that cause Pendred syndrome. Pendred syndrome and DFNB4 hearing loss fall on a spectrum of hearing impairment conditions that may also include other abnormalities.

Genetic profile

The majority of Pendred syndrome cases are caused by mutations in the *SLC26A4* gene. Located on chromosome 7q31, this gene tells the body how to make a specific protein called pendrin. The pendrin protein is responsible for transporting negatively charged elements (ions) such as iodide and chloride (forms of iodine and chlorine) within the thyroid and the inner ear as well. Changes within the *SLC26A4* gene create an altered form of pendrin protein that does not work properly and thus causes the symptoms of Pendred syndrome. Genetic researchers have identified at least 60 different types of alterations in the *SLC26A4* gene among different families. However, four of these are more common than the others, and it is estimated that approximately 75% of affected people have these common changes.

QUESTIONS TO ASK YOUR DOCTOR

- What is a goiter, and what causes the development of a goiter?
- Why is Pendred syndrome considered to be a genetic disorder?
- If someone in my family has had Pendred syndrome, what are the chances that my own children will also develop the condition?
- Are there tests that can be conducted, either before a child is born or while the child is still an infant, that will predict if the child will develop Pendred syndrome?

Pendred syndrome is inherited in an autosomal recessive manner. Autosomal means that males and females are equally likely to be affected. Recessive refers to a specific type of inheritance in which both copies of a person's gene pair (both alleles) need to be changed or altered in order for the condition to develop. In this situation, an affected individual receives an altered copy of the same gene from each parent. If the parents are not affected, they each have one working copy of the gene and one nonworking (altered) copy and are only carriers for Pendred syndrome. The chance that two carrier parents will have a child affected with Pendred syndrome is 25% for each pregnancy. They also have a 50% chance to have an unaffected child who is simply a carrier, and a 25% chance to have an unaffected child who is not a carrier, with each pregnancy.

Genetic research on the *SLC26A4* gene has revealed that different types of gene changes can lead to different symptoms. For example, changes that completely inactivate the pendrin protein have been seen among people with Pendred syndrome, whereas other types of alterations that only decrease the activity of pendrin have been found in people who have an inherited form of deafness called DFNB4. These individuals do have SNHL, but they do not develop goiter. Researchers suspect that the small amount of pendrin activity in these individuals likely prevented or delayed the symptoms of goiter. Greater than 80% of people with EVA and SNHL have one or more changes in the *SLC26A4* gene, even though they may not all have thyroid changes such as goiter or abnormal perchlorate discharge test results. Changes in the pendrin gene cause a number of overlapping conditions. These conditions range from Pendred syndrome (SNHL and thyroid changes) to SNHL with EVA.

Demographics

It is estimated that 10% of all hearing loss may be attributed to Pendred syndrome. It has been diagnosed in many different ethnic groups, including European, Japanese, East Indian, and other Caucasian groups, as well as among people of African descent. Inherited forms of congenital SNHL occur in approximately 1 of every 2,000 children. Males and females are both affected.

Signs and symptoms

Although the symptoms of Pendred syndrome can vary among different individuals, the findings may include the following:

- sensorineural hearing loss that is usually congenital
- thyroid changes such as goiter, abnormal perchlorate discharge test results, and/or hypothyroidism
- inner ear changes, such as enlarged vestibular aqueduct (EVA) or Mondini malformation
- altered vestibular function that leads to balance problems

Diagnosis

The diagnosis of Pendred syndrome is typically based upon the results from a variety of tests that measure hearing, thyroid appearance/function, inner ear structure, and balance. Sometimes the diagnosis is not made until a person with SNHL reaches adolescence or adulthood and develops thyroid problems such as goiter or hypothyroidism. These problems are usually detected by physical examination and blood tests, and thus help diagnose Pendred syndrome. Children who are born with SNHL often undergo special imaging tests such as CT or MRI scans. These may show inner ear changes that raise the question of possible changes in the *SLC26A4* gene, even if the children do not have thyroid problems. In each of these situations, genetic testing may provide useful information that can confirm the diagnosis of Pendred syndrome.

Genetic research testing can be done for people with suspected or known Pendred syndrome by studying their DNA. The laboratory can check for mutations in the *SLC26A4* gene. If this testing identifies an affected person's specific genetic changes, other people in the same family who are not affected may have their DNA examined as well. This can determine whether an unaffected person is a carrier for Pendred syndrome or not. In addition, testing could be done during a pregnancy if both of a baby's parents are carriers and have each had specific changes diagnosed in their DNA.

If genetic testing is done for people with known or suspected Pendred syndrome and the laboratory finds only one changed gene or no changes in the *SLC26A4* gene, the diagnosis of Pendred syndrome cannot be

confirmed. However, this does not rule out the possibility of Pendred syndrome. Sometimes this happens simply because the affected person has a very unique change in the *SLC26A4* gene that the lab cannot clearly identify.

Treatment and management

There is no known cure for Pendred syndrome. However, there are several ways to treat some of the symptoms.

Treatment and management of SNHL

Regular visits with an audiologist (a hearing specialist) and an ENT (a physician specializing in the ear, nose, and throat) are important for people with Pendred syndrome. Hearing tests are necessary to check for changes in hearing ability, especially if people have milder forms of hearing loss and have some ability to hear. Among people with milder forms of hearing loss, hearing aids and speech therapy may be useful. However, people with profound SNHL and their families usually benefit from sign language training, which provides a good method of communication. Some people with severe to profound forms of hearing loss may also consider a procedure called cochlear implantation, in which a small electronic device is surgically placed behind the ear (underneath the skin) and is attached to a wire that stimulates the inner ear. This may allow people to hear useful sounds.

Treatment and management of thyroid problems

Regular examinations by an endocrinologist (a physician specializing in the treatment of hormone problems) who is familiar with Pendred syndrome is important. People who develop goiter and/or hypothyroidism are sometimes treated with a medication called thyroxine, which is basically the hormone called T4. Other people with goiter have most of their thyroid surgically removed. However, this form of treatment is not a cure, and the remaining thyroid tissue can grow and redevelop into goiter again. Among some people, the goiter does not require treatment or it simply disappears on its own.

There are a number of support groups available that provide education, support, and advice to help people cope with the symptoms of SNHL and thyroid problems that often occur among individuals with Pendred syndrome.

Prognosis

Pendred syndrome does not cause a shortened lifespan for affected individuals. Those who develop hypothyroidism and do not seek treatment may experience a

variety of health problems including low energy level, weight gain, constipation, and dry skin. However, hypothyroidism and goiter can usually be well managed with medication or surgery. The degree of hearing loss that occurs is typically severe to profound from an early age and usually changes very little over the years. Among affected people who develop SNHL during childhood (after learning to speak), the degree of hearing loss can worsen over time. Sign language training (and sometimes cochlear implants) allow alternative methods of communication and thus help people reach their full potential. Support groups for people with hearing loss often help individuals with SNHL (whether due to Pendred syndrome or other causes) maintain and/or improve their quality of life as well.

Pervasive developmental disorders

Definition

The pervasive developmental disorders, or PDDs, are a group of childhood disorders that manifest during the first years of a child's life. They are marked by severe weaknesses in several areas of development, including social interaction and communication, and the appearance of stereotyped behavior patterns and interests. The PDDs are also known as autistic spectrum disorders (ASDs). As the phrase "spectrum disorder" suggests, persons with these disorders fall at different points along a fairly wide continuum of disabilities and associated disorders. As defined by the *Diagnostic and Statistical Manual of Mental Disorders*, also referred to as *DSM-5*, the pervasive developmental disorders include the following:

- autistic disorder
- Rett syndrome
- childhood disintegrative disorder (CDD)
- Asperger syndrome
- pervasive developmental disorder not otherwise specified (PDD-NOS)

Description

The PDDs form a diagnostic category intended to identify children with delays in or deviant forms of social, linguistic, cognitive, and motor (muscular movement) development. The category covers children with a wide variety of developmental delays of differing severity in these four broad areas. The precise cause(s) of the PDDs are still obscure, but are assumed to be abnormalities of the central nervous system.

Autistic disorder

Autistic disorder, or autism, was first described in 1943. Autistic children are characterized by severe impairment in their interactions with others and delayed or abnormal patterns of communication; about 50% of autistic children do not speak at all. These abnormalities begin in the first weeks of life; it is not unusual for the parents of an autistic child to say that they "knew something was wrong" quite early in the child's development. Another characteristic symptom has

been termed “insistence on sameness”; that is, these children may become extremely upset by trivial changes in their environment or daily routine—such as a new picture on the wall or taking a different route to the grocery store. Autistic children often make repetitive or stereotyped gestures or movements with their hands or bodies. Their behavioral symptoms may also include impulsivity, aggressiveness, temper tantrums, and self-biting or other forms of self-injury.

About 75% of children diagnosed with autism are also diagnosed with moderate intellectual disability (IQ between 35 and 50). Their cognitive skills frequently develop unevenly, regardless of their general intelligence level. A minority of autistic children have IQs above 70; their condition is sometimes called high-functioning autism, or HFA. In addition to intellectual disability, autism is frequently associated with other neurological or medical conditions, including encephalitis, phenylketonuria, tuberous sclerosis, fragile X syndrome, and underdeveloped reflexes. About 25% of autistic children develop seizure disorders, most often in adolescence.

Rett syndrome

Unlike autism, Rett syndrome has a very distinctive onset and course. The child develops normally during the first five months of life; after the fifth month, head growth slows down and the child loses whatever purposeful hand movements she had developed during the first five months. After 30 months, the child frequently develops repetitive hand-washing or hand-wringing gestures; over 50% of children with the disorder will develop seizure disorders. Rett syndrome is also associated with severe or profound intellectual disability. This disorder is diagnosed only in females.

Childhood disintegrative disorder (Heller’s syndrome)

Childhood disintegrative disorder, or CDD, was first described by an educator named Theodore Heller in 1908. He referred to it as dementia infantilis. Children with CDD have apparently normal development during the first two years of life. Between two and ten years of age, the child loses two or more previously acquired skills, including language skills, social skills, toileting, self-help skills, or motor skills. The child may also lose interest in his or her surroundings and often comes to “look autistic.” CDD has several different patterns of onset and development; it may develop rapidly (within weeks) or more slowly (over a period of months).

CDD is frequently associated with severe intellectual disability. In addition, children with CDD have a higher risk of seizures. CDD is occasionally associated with general medical conditions (metachromatic leukodystrophy or Schilder’s disease) that could account for the

KEY TERMS

Atypical personality development—Another term for pervasive development disorder (PDD-NOS). Other synonyms for this diagnostic category are atypical autism and atypical PDD.

Autistic psychopathy—Hans Asperger’s original name for Asperger syndrome. It is still used occasionally as a synonym for the disorder.

Autistic spectrum disorders—Another term for the pervasive developmental disorders.

GABAergic system—The system by which gamma-aminobutyric acid (GABA), the main neuro-inhibitory transmitter and its receptor, function within the brain during pre- and post-synaptic events to modulate ion channels.

Heller’s syndrome—Another name for Childhood Disintegrative Disorder (CDD). It is also sometimes called dementia infantilis.

Kanner’s syndrome—Another name for autism.

developmental losses, but in most cases there is no known medical cause of the child’s symptoms.

Asperger syndrome

Asperger syndrome (AS) was first identified in 1944 by a Viennese psychiatrist. It is sometimes called autistic psychopathy. AS is distinguished from autism by later onset of symptoms. These children usually develop normally for the first few years of life and retain relatively strong verbal and self-help skills. They are often physically clumsy or awkward, however, and this symptom may be noticed before the child starts school. AS is diagnosed most frequently when the child is between five and nine years of age. One of the distinctive features of Asperger syndrome is an abnormal degree of fascination or preoccupation with a limited or restricted subject of interest, such as railroad timetables, the weather, astronomical data, French verb forms, etc. In addition, the child’s knowledge of the topic reflects rote memorization of facts rather than deep understanding.

Unlike autism, AS does not appear to be associated with a higher risk of seizure disorders or such general conditions as fragile X syndrome.

Pervasive developmental disorder not otherwise specified

PDD-NOS is regarded as a “subthreshold” category, which means that it covers cases in which the child has

some impairment of social interaction and communication or has some stereotyped patterns of behavior but does not meet the full criteria for another PDD. PDD-NOS is sometimes referred to as atypical personality development, atypical autism, or atypical PDD. No diagnostic criteria specific to this category are provided in *DSM-5*. Little research has been done on children diagnosed with PDD-NOS because the condition has no clear definition. The available data indicate that children placed in this category are diagnosed at later ages than children with autism and are less likely to have mental impairment.

Genetic profile

Of the PDDs, autism has the best-documented genetic component, although more research is required. It is known that the degree of similarity in a pair of twins with respect to autism is significantly higher in identical than in fraternal twins. The likelihood of the biological parents of an autistic child having another child with the disorder is thought to be about 1:20. It is possible that the actual rate is higher, since many parents of one autistic child decide against having more children.

The genetic profile of Asperger syndrome is less well known, although the disorder appears to run in families—most commonly families with histories of depression or bipolar disorder. Rett syndrome is known only from case studies, so data about its genetic profile is not available. The same lack of information is true also of CDD—partly because the disorder was first reported in 1966 and has only been officially recognized since 1994, and partly because the condition has been frequently misdiagnosed.

Demographics

ASD is thought to affect 1 in 68 U.S. children. CDD is much less frequent, perhaps only a tenth as common as ASD. Rett syndrome is also very rare and is known only from case series reported in the medical literature. The incidence of Asperger syndrome is not definitely known, but some estimates put it between 0.36% and 0.71% of the general population.

Some of the PDDs are considerably more common in boys than in girls. The male-to-female sex ratio in autism is variously given as 4:1 or 5:1. Less is known about the incidence of Asperger syndrome, but one study reported a male/female ratio of 4:1. Initial studies of CDD suggested an equal sex ratio, but more recent data indicate that the disorder is more common among males. Rett syndrome, on the other hand, has been reported only in females.

Signs and symptoms

The signs and symptoms of each PDD are included in its description.

Diagnosis

The differential diagnosis of ASD is complicated by several factors. One is the wide variation in normal rates of children's development. In addition, because some of the symptoms of autism are present in intellectual disability, it can be difficult to determine which condition is present in a specific child, or whether both conditions are present. A definitive diagnosis of autism is rarely given to children under the age of three years. Delays or abnormal patterns in cognitive and social development can be more accurately assessed in children age three or four; children with AS or PDD-NOS may not be diagnosed until age five or later. A third factor is the tangled history of differential diagnosis of childhood disorders. Autism was first described by a physician named Leo Kanner in 1943. For several decades after Kanner's initial observations, researchers assumed that there was an association or continuity between autism in children and schizophrenia in adults. In fact, the term "autism" was first used to describe the self-focused thinking that characterizes schizophrenia; it was only later that the word was applied to the severe impairment of social behaviors that is a major symptom of autistic disorder. It took years of further research to establish clear diagnostic distinctions between autism and schizophrenia. Furthermore, the early assumption of a connection between autism and schizophrenia led to the hypothesis that autism was caused by painful experiences in early childhood. It is now known that autism and the other PDDs are essentially neurological disturbances.

Medical or laboratory testing

There are no brain imaging studies or laboratory tests that can be performed to diagnose a pervasive developmental disorder. The examiner may recommend a hearing test to rule out deafness as a possible cause of a child's failure to respond to the environment or a brain scan to rule out other physical conditions.

Diagnostic interviews

A PDD may be diagnosed by a pediatrician, pediatric neurologist, psychologist, or specialist in child psychiatry. The diagnosis is usually based on a combination of the child's medical and developmental history and clinical interviews or observations of the child. Children who cannot talk can be evaluated for their patterns of nonverbal communication with familiar as well as unfamiliar people. The parents may be asked to describe the child's use of eye contact, gestures, facial expressions, and body language. A clinical psychologist can administer special tests designed to evaluate the child's problem-solving abilities without the use of language.

Diagnostic questionnaires and other tools

The examiner may use a diagnostic checklist or screener such as the Childhood Autism Rating Scale, or CARS, which was developed in 1993. In addition, the Autism Research Institute (ARI) distributes a Form E-2 questionnaire that can be completed by the parents of a child with a PDD and returned to ARI. Form E-2 is not a diagnostic instrument as such but a checklist that assists ARI in the compilation of a database of symptoms and behaviors associated with autistic spectrum disorders. Parents who complete the form will receive a brief report about their child. Researchers expect that the database will help to improve the accuracy of differential diagnosis as well as contribute to more effective treatments for children with PDDs.

Treatment and management

The treatment and management of children with PDDs varies considerably according to the severity of the child's impairment and the specific areas of impairment. It is known that the GABAergic system is disrupted in many of these neurological disorders, and recent research findings in animal models of many of the aforementioned disorders have shown that drugs that target and modulate the GABAergic system have had encouraging outcomes and should be tested in clinical trials.

Medications

There are no medications that can cure any of the PDDs, and no single medication that is recommended for the symptoms of all children with PDDs. In addition, there are few comparative medication studies of children with ASD. The five sites (UCLA, University of Indiana, Ohio State, Yale, and the Kennedy-Krieger Institute) involved in the Research Units in Pediatric Psychopharmacology (RUPP) Program are currently conducting a study of risperidone in PDD children with behavioral problems. The RUPP sites are also testing medications approved for use in adults with self-injuring behaviors, anxiety, aggressive behavior, and obsessive-compulsive disorder on children with PDDs. This research is expected to improve the available treatments for children with these disorders.

Psychotherapy

The only PDD patients who benefit from individual psychotherapy are persons with AS or with HFA who are intelligent enough to have some insight into their condition. Typically, they become depressed in adolescence or adult life when they recognize the nature and extent of their social disabilities.

Educational considerations

Most children with AS and some children with high-functioning autism are educable. Many people with AS, in

QUESTIONS TO ASK YOUR DOCTOR

- What does the phrase "pervasive developmental disorders" mean?
- At what stage of a person's life do pervasive developmental disorders typically manifest?
- Are there medications or other types of treatments that can be used with pervasive developmental disorders?
- Are there organizations that can provide parents with additional information about any one or more of the most common pervasive developmental disorders?
- Have any therapies been found to be useful in treating autism or AS?

fact, successfully complete graduate or professional school. Only a small percentage of autistic children, however, complete enough schooling to be able to live independently as adults. Children with CDD must be placed in schools for the severely disabled.

Employment

Most children with AS can finish school and enter the job market. They do best in occupations that have regular routines or allow them to work in isolation. Only a few high-functioning autistic children are potentially employable.

Prognosis

The PDDs as a group are lifelong disorders, but the prognoses vary according to the child's degree of impairment. As a general rule, language skills and the child's overall IQ are the most important factors in the prognosis. Children with AS have the most favorable educational prognosis but usually retain some degree of social impairment even as adults. Of autistic children, only about one-third achieve partial or complete independence in adult life. The prognoses for Rett syndrome and CDD are worse than that for autism, as the skill levels of these children often continue to deteriorate. Some, however, make very modest developmental gains in adolescence. Lastly, current information about the prognoses of children with PDDs is derived from treatments given to patients in the 1970s or 1980s. As knowledge of effective treatments for PDDs continues to accumulate, children with these disorders will receive treatment earlier than they did two decades ago. It is likely that future prognoses for the PDDs will reflect these improvements.

and Sherrill Lathrop Macura, PhD

Peutz-Jeghers syndrome

Definition

Peutz-Jeghers syndrome (PJS) is named after two doctors who first studied and described it in 1921. It is an association of three very specific conditions in any one person. The first condition is the appearance of

freckles on parts of the body where freckles are not normally found. The second condition is the presence of multiple gastrointestinal polyps. The third condition is a risk, greater than the risk seen in the general population, of developing certain kinds of cancers.

Description

The freckles associated with PJS are dark brown, dark blue, or greenish black. In almost all people with PJS, these freckles are present at birth on the lining of the cheeks inside the mouth. By the time most children reach one or two years old, freckles develop around the lips, nostrils, eyes, anus, and genitals. This is in contrast to ordinary freckles, which are absent at birth and rarely develop in these locations. The freckles seen in PJS are sometimes called macules (discolored spot or patch on the skin of various colors, sizes, and shapes) or areas of hyperpigmentation (increased pigmentation of the skin).

Some people with PJS also have these freckles on the palms of their hands or feet or on their fingertips. Freckles may merge together. The freckles on the skin often fade or disappear by adolescence, but the freckles inside the mouth generally remain throughout the person's life.

Gastrointestinal polyps can develop in children as young as one or two years old. The age at which polyps appear and the number of polyps vary widely from patient to patient. Polyps can occur in infants and cause spasms and pain in the abdomen. On average, polyps appear by the time a child with PJS is ten years old. There may be anywhere from dozens to hundreds of polyps throughout the gastrointestinal tract. For this reason, PJS is sometimes called polyposis, which means "too many polyps." Most PJS polyps occur in the small intestine, but they can also develop in the esophagus, stomach, and colon. In some people with PJS, polyps have been found in the mouth or nose.

The polyps seen in PJS have a unique structure. They consist of overgrowths of normal tissue that smooth muscle bands of the stomach and intestines run through. This kind of overgrowth is called a hamartoma. Consequently, PJS is sometimes called hamartomatous intestinal polyposis. A hamartoma is a noncancerous tumor, and hamartomatous polyps are not cancerous. However, they can take up too much space, causing obstruction, pain, and even bleeding. They can also become cancerous, or malignant, if a genetic change results in uncontrolled cell growth.

It is this potential for malignant change that increases cancer risk in people with PJS. As might be expected, the gastrointestinal tract is the most common site for cancer in people with PJS. The small intestine,

stomach, gallbladder, pancreas, colon, and rectum are all susceptible. However, cancer can also occur outside the gastrointestinal tract. When this happens, the sites most likely to be involved are the breasts, ovaries, uterus, cervix, or testicles.

PJS does not affect intelligence or behavior.

Genetic profile

Researchers have identified the gene responsible for about seven out of ten PJS cases. The gene is named *STK11*, and it is located at the 19p13 site on chromosome 19. In some older studies, the same gene is referred to as *LKB1*. Researchers have connected more than 50 different *STK11* mutations to cases of PJS.

However, some cases do not appear to be connected to *STK11*. As a result, PJS qualifies as a genetically heterogeneous condition; this means that it has more than one known genetic cause. Research continues in order to locate the genes involved in the three out of ten cases not related to *STK11*.

When linked to *STK11*, PJS is an autosomal dominant disorder. This means that the condition occurs even when an individual inherits only one abnormal copy of *STK11* from either parent. In some people with PJS, the condition is limited to freckles on the lining of the cheeks inside the mouth. Many of these people also have gastrointestinal polyps. One abnormal copy of *STK11* also increases a person's risk of developing the kinds of cancer associated with PJS.

Since only one abnormal copy of *STK11* is needed to cause PJS, most people with the condition still have one normal copy of the gene. One normal copy is usually enough to protect against the kinds of cancer associated with PJS. This is because *STK11* is a tumor suppressor gene. A properly working tumor suppressor gene makes a product that controls cell growth. Since cancer is the result of uncontrolled cell growth, tumor suppressors prevent cancer. Even one working copy of *STK11* protects against cancer.

The reason people with PJS have an increased risk of developing cancer is that one *STK11* gene is already abnormal at birth. If damage to the normal *STK11* gene occurs later, the ability to control cell growth is lost, leading to the kinds of cancers associated with PJS.

Damage to normal genes can occur in anyone. However, it generally takes less time to damage one gene than two genes. Therefore, people with PJS are likely to develop cancer at earlier ages than are people born with two normal *STK11* genes.

About half of all PJS cases occur because a child inherits a changed gene from a parent with PJS. The other

KEY TERMS

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes.

Colon—The large intestine.

Colonoscopy—Procedure for viewing the large intestine (colon) by inserting an illuminated tube into the rectum and guiding it up the large intestine.

Endoscopy—A slender, tubular optical instrument used as a viewing system for examining an inner part of the body and, with an attached instrument, for biopsy or surgery.

Enteroscopy—A procedure used to examine the small intestine.

Esophagus—The part of the digestive tract that connects the mouth and stomach; the food pipe.

Gastrointestinal—Concerning the stomach and intestine.

Hamartoma—An overgrowth of normal tissue.

Hyperpigmentation—An abnormal condition characterized by an excess of melanin in localized areas of the skin, which produces areas that are much darker than the surrounding unaffected skin.

Laparoscopy—A diagnostic procedure in which a small incision is made in the abdomen and a slender, hollow, lighted instrument is passed through it. The doctor can view the ovaries more closely through the laparoscope and, if necessary, obtain tissue samples for biopsy.

Macule—A flat, discolored spot or patch on the skin.

Mammogram—A procedure in which both breasts are compressed/flattened and exposed to low doses of x-rays, in an attempt to visualize the inner breast tissue.

Polyp—A mass of tissue bulging out from the normal surface of a mucous membrane.

Polypectomy—Surgical removal of polyps.

Tumor suppressor gene—Genes involved in controlling normal cell growth and preventing cancer.

half are due to a mutation in the cell from which the child develops. A person born with one abnormal gene can pass that gene on to the next generation. One out of two of this person's children will inherit the gene. In addition, if PJS is inherited, each parent or sibling of the affected person has a one out of two chance of carrying the gene.

Demographics

PJS occurs in about 1 out of 25,000 to 300,000 people. It affects males and females of all races and ethnic groups. The particular genetic mutation may differ among groups and even among families within a group.

Signs and symptoms

The first sign of PJS, freckling inside the mouth or in unusual places, generally appears in infants. Polyps usually begin causing symptoms by age ten. Polyps make themselves known in a variety of ways. They can cause abdominal pain or intestinal bleeding. Sometimes the blood loss leads to anemia (a condition where there is a reduction in circulating red blood cells, the amount of hemoglobin, or the volume of packed red cells). Polyps sometimes protrude outside the rectum or obstruct the gastrointestinal tract. Untreated obstructions can be fatal.

Tumors may appear in childhood. Children as young as six may develop a particular kind of ovarian or testicular tumor that causes early puberty. Affected boys sometimes begin to develop breasts. These tumors can be noncancerous, but they have the potential to become malignant.

A few patients develop malignant tumors in the first decade of life. Other patients have stomach, breast, or cervical cancer before age 30. The specific form of cervical cancer is extremely rare in the general population.

Diagnosis

Because the peculiar freckling seen in PJS is present so early, doctors familiar with the condition may suspect PJS even before other symptoms occur. This is ideal, since early diagnosis greatly improves the prognosis.

Many children or young adults come to medical attention due to the pain, bleeding, or anemia caused by polyps. Doctors can confirm the presence of multiple polyps using a variety of methods. Noninvasive methods include ultrasound and x-ray techniques. Invasive methods use a tube and an optical system to conduct an internal inspection of the gastrointestinal tract. These methods include endoscopy, enteroscopy, and colonoscopy, all of which involve entry to the gastrointestinal tract through an existing body orifice. Laparoscopy is another invasive method; it involves entering the gastrointestinal tract through an incision in the abdomen. All invasive methods allow for removal of polyps found during the exam. Once the polyps are removed and examined, their unique structure and large number lead to diagnosis of PJS. The average age at PJS diagnosis is 17.

Freckles and polyps occur in more than 95% of people with PJS. Sometimes, though, the freckles fade before

symptoms of polyps appear. It is important to take a medical history in order to determine if freckles were present on the skin earlier in life. The doctor should also examine the lining of the cheeks inside the mouth, where freckles are likely to remain throughout life.

The number and intensity of the freckles do not predict the severity of gastrointestinal symptoms or the risk of developing cancer. Any patient diagnosed with PJS needs regular cancer screening.

The presence of the rare cervical cancer, ovarian tumor, or testicular tumor associated with PJS leads to diagnosis in some patients.

A family history of PJS is suspicious but not required for diagnosis, since PJS can occur as a new mutation. Once PJS has occurred in a family, parents, siblings, and children of the affected person should seek medical attention.

Genetic testing is available to confirm clinical diagnosis or to determine if a person carries an abnormal *STK11* gene. Using a swab, cells are removed from the lining of the cheeks inside the mouth. DNA is extracted and analyzed. The test confirms PJS if analysis reveals an *STK11* mutation. However, the test cannot rule out PJS if an *STK11* mutation is not found, since some cases are due to other genetic causes.

Prenatal diagnosis of PJS is possible only if the family's specific *STK11* mutation has previously been identified. Prenatal testing is done by amniocentesis or chorionic villus sampling. Amniocentesis involves removal of a small amount of amniotic fluid from the uterus. Chorionic villus sampling involves removal of a small sample of placental tissue. In either case, DNA is extracted from sample cells and analyzed.

Even without genetic testing, diagnosis of PJS is fairly straightforward. Although several other conditions cause multiple intestinal polyps or hyperpigmentation, the distinctive structure of PJS polyps and the unusual location of PJS freckles eliminate other conditions from consideration.

Treatment and management

For people with a family history of PJS, treatment and management of the condition may begin even before diagnosis. If PJS freckles do not appear at birth and if there are no symptoms of polyps, affected families may desire genetic testing for their children.

For most genetic conditions, testing is delayed until children are old enough to understand the disease, its consequences, and the advantages and disadvantages of genetic screening. However, since PJS can affect children under the age of ten, any delay could be risky. Therefore,

it is appropriate for families with PJS to consider genetic testing for their children. Children who do carry an *STK11* mutation can begin a preventive care program immediately, and children who do not carry an *STK11* mutation can avoid unnecessary intervention.

The decision to seek genetic testing requires careful consideration. A positive test for PJS cannot predict the precise age of onset, symptoms, severity, or progress of the condition. A genetic counselor can assist interested family members as they confront the medical, social, personal, and economic issues involved in genetic testing.

Parents, siblings, and children of people with *STK11* mutations may not wish to undergo genetic testing. In this case, they should have a thorough clinical exam to confirm or rule out PJS. The exam includes a careful inspection for freckles. In addition, people age ten or older require gastrointestinal screening, abdominal ultrasound, and a blood test for anemia. Males over age ten should have a testicular exam. Females should have a pelvic exam and ultrasound, Pap smear, and breast exam annually, by age 20. Women age 35 or older should have a mammogram.

For people with no family history of PJS, treatment and management usually begin when PJS is diagnosed.

In past generations, polyp complications such as intestinal obstruction or hemorrhage were a frequent cause of death in PJS patients. However, treatment of polyps is now widely available. The doctor performs a polypectomy to remove the polyps. Polypectomy may be done at the same time as endoscopy, enteroscopy, colonoscopy, or laparoscopy. Anesthesia is used to make the patient more comfortable.

To manage polyps and screen for early signs of cancer, all people who have PJS and are age ten or older need preventive screening on a regular basis. Gastrointestinal screening is the first test, and polypectomy is performed at the same time. Also at age ten, the person begins an annual screening program that includes a blood test for anemia and a testicular exam for boys.

After age ten, gastrointestinal screening with polypectomy is performed every two years.

By age 20, annual screening is expanded to include an abdominal ultrasound for both males and females, as well as a pelvic exam and ultrasound, Pap smear, and breast exam for females.

By age 35, a woman with PJS should have her first mammogram; mammograms should be repeated every two years until the woman is 50. At that time, a mammogram should be added to the annual screening program.

Polyps found during preventive screening are immediately treated by polypectomy. Preventive screening

QUESTIONS TO ASK YOUR DOCTOR

- Are there other names by which Peutz-Jeghers syndrome is known?
- What are the characteristic signs and symptoms of Peutz-Jeghers syndrome?
- What are the most serious medical conditions associated with Peutz-Jeghers syndrome?
- What is the long-term prognosis for a child diagnosed with this genetic disorder?

may also reveal suspicious growths in the gastrointestinal tract or outside of it. These growths require urgent medical attention, since they may be precancerous or cancerous. Diagnosis may require additional tests or biopsy. Treatment is determined on an individual basis, depending on the patient's medical condition and the nature of the growth.

Some people with PJS do not care for the appearance of their freckles. Removal of freckles using laser therapy is an available treatment option.

Many people with PJS find the preventive screening program psychologically exhausting, and young children can find it frightening. These individuals often need the ongoing support and understanding of friends, family, and community. Several organizations composed of people with PJS, their family members, and medical professionals offer additional support and information. There is also an online support group dedicated to PJS.

People with PJS may find it helpful to consult a genetic counselor. Genetic counselors can provide up-to-date information about PJS research, therapy, and management.

Prognosis

Early detection of PJS is the key to its prognosis. Polyps cause less pain and fewer complications when found and removed early. In addition, the patient can begin a preventive screening program at an early age. This increases the likelihood of finding suspicious growths before they become malignant.

Unless they undergo regular screening, people with PJS have a one in two chance of dying from cancer before the age of 60. Moreover, the average age of cancer death in unscreened people with PJS is 39.

Researchers are actively investigating cancer screening, prevention, and treatment methods. In the meantime,

regular preventive screening may reduce the illness and premature death associated with PJS.

Pfeiffer syndrome

Definition

Pfeiffer syndrome is one of a group of disorders defined by premature closure of the sutures of the skull, resulting in an abnormal skull shape. People affected with these conditions, known as craniosynostosis syndromes, may also have differences in facial structure and hand and foot abnormalities. The defining features of Pfeiffer syndrome are abnormalities of the hands, feet, and shape of the skull.

Description

Pfeiffer syndrome is a complex disorder. Three subtypes of Pfeiffer have been defined based on symptoms. The syndrome is caused by a mutation (alteration) in either of two different genes. As the genes that cause craniosynostosis syndromes were discovered throughout the 1990s, scientists realized that these syndromes have overlapping underlying causes. Crouzon, Apert, Jackson-Weiss, and other syndromes are related to Pfeiffer

syndrome by genetic causation as well as associated symptoms. Noack syndrome, once thought to be a separate condition, is now known to be the same as Pfeiffer syndrome. Acrocephalosyndactyly, type V (ACS5) and Noack syndrome both refer to Pfeiffer syndrome.

Genetic profile

Pfeiffer syndrome is an autosomal dominant condition. Every person has two copies of every gene, one maternally inherited and one paternally inherited. Autosomal dominant conditions occur if a person has a change in one member of a gene pair. The chance for an affected individual to have an affected child is 50% with each pregnancy.

A person who has an autosomal dominant condition may have it because he or she inherited the altered gene from an affected parent or because of a new mutation. A new mutation occurs when the gene is altered for the first time in that individual. A person with an autosomal dominant condition due to a new mutation is the first person in his or her family to be affected.

Nearly all individuals with Pfeiffer syndrome types 2 and 3 described in the medical literature have new mutations. When a person has a new mutation, his or her parents are usually not at risk to have another child with the condition. The milder form, Pfeiffer syndrome type 1, is more likely to be inherited. When the mutation is inherited, the child's symptoms are often similar to those of the affected parent. Pfeiffer syndrome is fully penetrant. This means that all of the individuals who have the mutated gene associated with the condition are expected to have symptoms. In other words, the mutant gene is always expressed.

The two genes that cause Pfeiffer syndrome are called *FGFR1* and *FGFR2*. *FGFR1* is on chromosome 8, at the location 8p11.23-p11.22. *FGFR2* is on chromosome 10 at the location 10q26. These genes are members of a group of genes called the fibroblast growth factor receptors.

Fibroblasts play an important role in the development of connective tissue (e.g., skin and bone). Fibroblast growth factors (FGFs) stimulate certain cells to divide, differentiate (specialize to perform a specific function different than the function of the original cell), and migrate. FGFs are important in limb development, wound healing and repair, and other biological processes. FGFs communicate with targeted cells through the action of the fibroblast growth factor receptors. Fibroblast growth factor receptors (FGFRs) on the targeted cells bind the FGFs and relay their message within the cell.

In 2012, over 100 conditions were known to be caused by mutations in the four *FGFR* genes. Mutations

KEY TERMS

Craniosynostosis—Premature, delayed, or otherwise abnormal closure of the sutures of the skull.

Fibroblast growth factor—A type of gene that codes for a cell membrane receptor involved in normal bone growth and development.

Fibroblast growth factor receptor gene—Proteins that are important in such functions as the growth of new blood vessels (angiogenesis), in wound healing, and embryonic growth.

Gene—A building block of inheritance that contains the instructions for the production of a particular protein and is made up of a molecular sequence found on a section of DNA. Each gene is found at a precise location on a chromosome.

Suture—A “seam” that joins two surfaces together.

in *FGFR2* may cause Pfeiffer syndrome as well as Apert, Jackson-Weiss, and Crouzon syndromes. Nonetheless, a parent with Pfeiffer syndrome is at risk to have a child with Pfeiffer but is not at risk to have a child with Apert, Crouzon, or Jackson-Weiss syndromes. Because family members in multiple generations all have the same condition, the condition is said to “breed true” within families. A few exceptions—families with more than one *FGFR*-associated condition—are reported in the medical literature.

A given genetic condition may be associated with mutations in one particular gene, and mutations in a given gene may cause only one genetic condition. Alternatively, mutations in a gene may be associated with more than one genetic condition, and a particular genetic condition may be caused by any mutation in a number of multiple genes. *FGFR2* causing both Pfeiffer and Apert syndromes is an example of the former; *FGFR1* and *FGFR2* causing Pfeiffer syndrome is an example of the latter. Various mutations of a particular gene are called alleles. Sometimes a gene causes different genetic conditions because each allele leads to a specific set of symptoms.

The exact same mutation in the *FGFR2* gene may cause Pfeiffer syndrome in one family and cause a different craniosynostosis syndrome in another family. However, each family continues to have the same symptoms (the conditions breed true in each family). Differing effects of genes are sometimes explained by differing environmental influences and by differing interactions with other genes. However, the diverse effects of the

FGFR2 gene probably have a more specific explanation/mechanism. The underlying reasons for these phenomena may be explained when fibroblast growth factors and their receptors are better understood. At that time, criteria defining various craniosynostosis syndromes (e.g., Pfeiffer, Crouzon, and Jackson-Weiss) may be reexamined and revised.

Demographics

The incidence of Pfeiffer syndrome is approximately 1 in 100,000. The incidence of craniosynostosis is 1 in 2,000 to 1 in 2,500, which includes syndromic and nonsyndromic cases. In nonsyndromic cases, the craniosynostosis is an isolated finding; no other abnormalities are present. Nonsyndromic craniosynostosis is much more common than syndromic craniosynostosis. Usually, isolated craniosynostosis is sporadic (not familial). Mutations in ten different genes are associated with the development of some form of craniosynostosis.

Signs and symptoms

Individuals with Pfeiffer syndrome have a high forehead, a tower-shaped skull, and broad, deviated thumbs and great toes. The symptoms of type 1 are milder than those of types 2 and 3. Undergrowth of the midface leads to down-slanting, low-placed, widely spaced eyes; a small upper jaw bone; and a low nasal bridge. The larynx (voice organ below the base of the tongue) and the pharynx (tube that connects the larynx to the lungs) may be abnormal. Additional symptoms include a projecting chin, divergent visual axes, abnormalities of the passage between the nose and the pharynx, and hearing loss. Fingers and toes may be short and/or partially grown together. The palate may be especially high, and teeth may be crowded. In type 2, the elbow joint is frozen in place.

The skull is composed of many bones that fuse when the brain has finished growing. If the bones of the skull fuse prematurely (craniosynostosis), the skull continues to grow in an abnormal pattern. The places where the bones of the skull fuse are called sutures.

The suture that fuses prematurely in Pfeiffer syndrome is the coronal suture. This suture separates the frontal bone of the skull from the two middle bones (called the parietal bones). When the coronal suture closes prematurely, upward growth of the skull is increased, and growth toward the front and back is decreased. Sometimes the sagittal suture will also be fused prematurely in individuals with Pfeiffer syndrome. This suture separates the right and left sides of the middle of the skull. If both the coronal and sagittal sutures fuse prematurely, the skull develops a somewhat cloverleaf

shape. Individuals with Pfeiffer type 2 have cloverleaf skulls more often than individuals with types 1 and 3.

The coronal suture is also fused prematurely in Crouzon, Jackson-Weiss, Apert, and Beare-Stevenson syndromes. The thumbs and big toes are normal in Beare-Stevenson and Crouzon syndromes. Additional associated abnormalities distinguish Apert and Jackson-Weiss syndromes.

Serious complications of Pfeiffer syndrome include respiratory problems and hydrocephalus. Hydrocephalus is excessive fluid in the brain, which leads to mental impairment if untreated. Breathing problems may be caused by trachea abnormalities or be related to undergrowth of the midface. Some individuals may require an incision in the trachea (tracheostomy). Serious complications are more common in Pfeiffer types 2 and 3. Individuals with types 2 and 3 are severely affected and often do not survive past infancy. Death may result from severe brain abnormalities, breathing problems, prematurity, and surgical complications. Even without accompanying hydrocephalus, developmental delays and intellectual disability are common (in types 2 and 3). Lower displacement of the eyes may be so severe that the infant is unable to close his or her eyelids. Individuals with types 2 and 3 may also have seizures. Intellect is usually normal in Pfeiffer type 1.

Diagnosis

The diagnosis of Pfeiffer syndrome is initially based on clinical findings (symptoms) and is confirmed by genetic testing.

Often the doctor can determine which cranial suture closed prematurely by physical examination. For confirmation, an x-ray or computerized tomography (CT) scan of the head may be performed. Determining which suture is involved is crucial in making the correct craniosynostosis diagnosis.

Craniosynostosis may be caused by an underlying genetic abnormality, or it may be due to other, nongenetic factors. In Pfeiffer syndrome, the tissue itself is abnormal and causes the suture to fuse prematurely. The doctor will consider nongenetic causes of craniosynostosis. These secondary causes include external forces such as abnormal head positioning (in the uterus or in infancy) and a small brain.

Genetic testing may be useful for prenatal diagnosis, for confirmation of the diagnosis, and to provide information to other family members. Mutations are not detected in all individuals with Pfeiffer syndrome. People with Pfeiffer syndrome due to a mutation in the *FGFR1* gene may have less severe abnormalities than people who have Pfeiffer due to mutations in the *FGFR2* gene.

QUESTIONS TO ASK YOUR DOCTOR

- Please describe the process that occurs during craniosynostosis.
- Why is Pfeiffer syndrome considered a genetic disorder?
- How are the major symptoms of Pfeiffer syndrome treated?
- What are the most current therapies in use to treat the symptoms of Pfeiffer syndrome?

Prenatal diagnosis is available by chorionic villus sampling (CVS) or amniocentesis if a mutation has been identified in the affected parent. Amniocentesis is performed after the 15th week of pregnancy, and CVS is usually performed in the 10th and 12th weeks of pregnancy. A parent with Pfeiffer syndrome has a 50% chance of passing it to his or her offspring.

Craniosynostosis may be visible by fetal ultrasound. Conditions caused by mutations in the *FGFR* genes account for only a small portion of craniosynostosis. Assuming that the fetus does not have a family history of one of these conditions, genetic testing for the *FGFR* genes is unlikely to provide useful additional information.

Treatment and management

Children with Pfeiffer syndrome usually see a team of medical specialists at regular intervals. This team typically includes plastic surgeons; neurosurgeons; orthopedists; ear, nose, and throat doctors (otolaryngologists); dentists; and other specialists. The affected person may see the specialists all at once in a craniofacial clinic at a hospital. Many physical problems must be addressed. Developmental, psychosocial, and financial issues are additional concerns. Treatment is aimed at the symptoms, not the underlying cause. Even if craniosynostosis is discovered prenatally, only the symptoms can be treated.

Multiple surgeries are usually performed to progressively correct the craniosynostosis and to normalize facial appearance. A team of surgeons is often involved, including a neurosurgeon and a specialized plastic surgeon. The timing and order of surgeries vary. Patients with syndromic craniosynostosis often require surgery earlier than patients with nonsyndromic craniosynostosis. The first surgery is usually performed early in the first year of life, even in the first few months.

Additional surgeries may be performed for other physical problems. Limb abnormalities often are not

correctable. If the limb malformations do not lead to a loss of function, surgery is usually not required. Fixation of the elbow joints may be partially corrected, or at least altered to enable better functioning.

Hydrocephalus, airway obstruction, hearing loss, incomplete eyelid closure, and spine abnormalities require immediate medical attention.

Prognosis

The prognosis for an individual is based on the symptoms he or she has. Individuals with Pfeiffer syndrome type 1 have a better prognosis than individuals with types 2 or 3. But the designation of type is based on that person's symptoms.

Although people with Pfeiffer syndrome may not obtain a completely normal appearance, significant improvement is possible. Timing the surgeries correctly is an important factor in whether they are successful and whether repeat surgeries are required.

Although Pfeiffer syndrome is rare, craniosynostosis is relatively common. Multiple agencies and organizations exist to help families face the challenges of having a child with craniosynostosis and facial differences. The identification of the *FGFR* genes that cause Pfeiffer (and other) craniosynostosis syndromes has promoted research into the underlying process that causes Pfeiffer syndrome. It will be another enormous challenge to go from understanding the process to treating the process. When the process that causes Pfeiffer and related conditions is better understood, a much clearer knowledge of human development in general will also be established.

Pharmacogenetics

Definition

Pharmacogenetics is one of the newest subspecialties of genetics. It deals with the relationship between inherited genes and the ability of the body to metabolize drugs. The study of pharmacogenetics investigates how genetic factors affect the function of drugs or how the body reacts to drugs.

Description

Medicine today relies on the use of therapeutic drugs to treat disease, but one of the longstanding problems has been the documented variation in patient response to drug therapy. The "recommended" dosage is usually established at a level shown to be effective in 50% of a test population, and based on the patient's initial response the dosage may be increased, decreased, or discontinued. In rare situations the patient may experience an adverse reaction to the drug and be shown to have a pharmacogenetic disorder. The unique feature of this group of diseases is that the problem does not occur until after the drug is given, so a person may have a pharmacogenetic defect and never know it if the specific drug required to trigger the reaction is never administered.

Adverse reactions

Consider the case of a 35-year-old male who is scheduled for surgical repair of a hernia. The patient is otherwise in excellent health and has no family history of any serious medical problems. After entering the operating theater, an inhalation anesthetic and/or muscle relaxant is administered to render the patient unconscious. Unexpectedly, there is a significant increase in body temperature, and the patient experiences sustained muscle contraction. If this condition is not reversed promptly it can lead to death. Anesthesiologists are now very familiar with this type of reaction, but it occurs only rarely and uniquely identifies the patient as having malignant hyperthermia, a rare autosomal dominant disorder that affects the body's ability to respond normally to anesthetics. Once diagnosed with malignant hyperthermia, it is quite easy to avoid future episodes by simply using a different type of anesthetic when surgery is necessary, but it often takes one negative and potentially life-threatening experience to know the condition exists.

An incident that occurred in the 1950s further shows the diversity of pharmacogenetic disorders. During the Korean War, service personnel were deployed in a region of the world where they were at increased risk for malaria. To reduce the likelihood of acquiring that disease the antimalarial drug primaquine was administered prophylactically. Shortly thereafter, approximately 10% of the African-American servicemen were diagnosed with acute anemia, and a smaller percentage of soldiers of Mediterranean ancestry showed a more severe hemolytic anemia. Investigation revealed that the affected individuals had a mutation in the glucose 6-phosphate dehydrogenase (*G6PD*) gene. Functional *G6PD* is important in the maintenance of a balance between oxidized and reduced molecules in the cells, and under normal circumstances a mutation that eliminates the normal enzyme function can be compensated for by other cellular processes. However, mutation carriers are compromised when their cells are stressed, such as when the primaquine is administered. The system becomes overloaded and results in oxidative damage to red blood cells and anemia. Clearly, both the medics who administered the primaquine and the men who took the drug were unaware of the potential consequences. Fortunately, once the drug treatment was discontinued the individuals recovered.

Research efforts

Drugs are essential to modern medical practice, but as in the cases of malignant hyperthermia and *G6PD* deficiency, it has become clear that not all individuals respond equally to each drug. Reactions can vary from positive improvement in the quality of life to life-threatening episodes. Annually in the United States, there are over two

KEY TERMS

Drug metabolism—Chemical modification or breakdown of drugs. This usually occurs through the activity of specialized enzymatic pathways.

Metabolic pathways—A series of chemical reactions that happen in a cell that modify an initial substrate in sequential steps through the activity of specialized proteins called enzymes.

million reported cases of adverse drug reactions and a further 100,000 deaths per year as a result of drug treatments. The Human Genome Project and other research endeavors are now providing information that is allowing a better understanding of the underlying causes of pharmacogenetic anomalies with the hope that eventually the number of negative episodes can be reduced.

Research on one enzyme family is beginning to revolutionize the concepts of drug therapy. The cytochrome P450 system is a group of related enzymes that are key components in the metabolic conversion of over 50% of all currently used drugs. Studies involving one member of this family, CYP2D6, have revealed the presence of several polymorphic genetic variations that result in different clinical phenotypes with respect to drug metabolism. These variations are termed poor, intermediate, extensive, and ultra with respect to how they metabolize certain drugs. For example, a poor metabolizer has difficulty converting the therapeutic drug into a useable form, so the unmodified chemical will accumulate in the body and may cause a toxic overdose. To prevent this from happening the prescribed dosage of the drug must be reduced.

An ultra metabolizer, on the other hand, shows exceedingly rapid breakdown of the drug to the point that the substance may be destroyed so quickly that therapeutic levels may not be reached and the patient may never show any benefit from treatment. In these cases switching to another type of drug that is not associated with CYP2D6 metabolism may prove more beneficial.

The third phenotypic class, the extensive metabolizers, is less extreme than the ultra metabolism category but nevertheless presents a relatively rapid turnover of drug that may require a higher than normal dosage to maintain a proper level within the cells. The intermediate phenotype falls between the poor and extensive categories and gives reasonable metabolism and turnover of the drug. This is the group for whom most “recommended” drug dosages appear to be appropriate.

The elucidation of the four different metabolic classes has clearly shown that the usual “one size fits all” recommended drug dose is not appropriate for all individuals. In the future it will become increasingly necessary to know the patient’s metabolic phenotype with respect to the drug being given to determine the most appropriate regimen of therapy for that individual.

Future applications

Based on current studies it is possible to envision many different applications of pharmacogenetics. In addition to providing patient-specific drug therapies, pharmacogenetics will aid in the clinician’s ability to predict adverse reactions before they occur and identify the potential for drug addiction or overdose. New tests will be developed to monitor the effects of drugs and new medications will be found that specifically target a particular genetic abnormality. Increased knowledge in this field should provide a better understanding of the metabolic effects of food additives, work-related chemicals, and industrial by-products. In time, these advances will improve the practice of medicine and become the standard of care.

Pharmacogenomics

Definition

Within the emerging field of precision medicine, pharmacogenomics (also called pharmacogenetics) studies how individual genetic variation affects

drug-treatment outcomes. Pharmacogenomics research helps physicians select the most effective treatments for some patients by studying how certain gene variants affect the safety of medications and how well they will work. A pharmacogenomic test looks for variations (mutations) in a person’s genes that can influence how their body reacts to certain medications. For example, it can test to see how much of a certain medication they might need, if any medications might be dangerous, and which medications might work better than others.

Description

People respond differently to certain medications partially because of our unique genetic makeup. Advances in this field, have led to genetic tests that can help doctors health providers the optimal medication and best dose for a patient.

Pharmacogenomics looks at gene variants that affect how the body breaks down and uses a drug (pharmacokinetics) and how well the body responds to the drug (pharmacodynamics). Pharmacokinetics includes: absorption, distribution, metabolism, and excretion (ADME). Absorption is how the drug enters the bloodstream. Distribution describe where the drug goes in the body after it is absorbed and how much reaches different parts of the body. Metabolism is how the body breaks down a drug and what products the drug is broken down into. Some of these products can have a particular action on the body. Drugs are mainly metabolized in the liver but some drugs are metabolized by other organs like the kidneys, lungs and intestines. Excretion describes how the drug leaves the body.

Gene variants can affect active drugs and prodrugs in different ways. An active drug is already active in the form that it is taken. The active drug usually becomes inactivated when it is converted into one or more compounds (metabolized). A prodrug is a medication that the body needs to metabolize in order for it to work. Prodrugs need to be metabolized to form a compound that can be used by the body.

Plavix, which is used to prevent heart problems, is an example of a prodrug. Normally it is converted to a compound that the body can use. About 30% of people have a variant in the CYP2C19 gene that prevents their body from properly breaking down Plavix into an active drug. Since Plavix does not work very well for people with this variant, other medications might be recommended.

Categories of drug response

Pharmacogenomic tests typically classify people into certain categories for each drug analyzed based on the type of variant that they have and the expected effect.

KEY TERMS

Cell—Building block that provides structure to the body and performs all the functions of the body. Cells contain genetic information and can copy themselves. The four main types of cells are: skin, nerve, muscle and connective tissue.

DNA (deoxyribonucleic acid)—The genetic material that contains the instructions for creating proteins.

DNA base—One unit in a DNA sequence. The four DNA bases are adenine (A), guanine (G), thymine (T) and cytosine (C). The sequence of these bases is the genetic code which contains the instructions for creating proteins.

DNA sequence—The sequence of DNA bases that contains the instructions for creating proteins. A three-base sequence in the DNA contains the instructions for making a particular amino acid. For example, CGC codes for the amino acid alanine. Proteins are made up of one or more amino acids strung together. The instructions for a particular protein are made up of a number of three-base sequences. Because DNA is double stranded it has two complementary sequences where the bases pair up together. C always pairs with G and A always pairs with T. An example double stranded DNA sequence for alanine is GCG/CGC.

Gene—A sequence of bases in a DNA sequence that contains the instructions for a protein.

Genome—The complete set of genetic instructions of an organism.

Metabolized—When a drug is converted into one or more compounds.

Pathogenic variant—Any change in the sequence of a genome that causes disease.

Pharmacodynamics—Study of how a drug affects the body.

Pharmacokinetics—Study of how the body breaks down and uses a drug.

Ribonucleic acid (RNA)—The genetic material that is involved in creating proteins. The DNA sequence that contains a gene needs to be transcribed into a single stranded molecule called messenger RNA (mRNA). In the RNA sequence, a base called uracil (U) replaces thymine (T) when it is found in the DNA sequence.

Single nucleotide polymorphism (SNP)—A variation in a single base pair in a genetic sequence.

Tissue—Made up of cells that have a common function. The four types of tissue are: connective, epithelial (skin), muscle and nervous tissue.

To sequence (verb)—Figure out the sequence of bases in genetic material like DNA or RNA.

Variant—Change in the sequence of a genome.

The expected effect will differ if it is a prodrug or active drug. These categories include:

- **Poor metabolizers.** People who break down a medication very slowly. If the medication is a prodrug then the drug may not work very well. If the medication is an active drug then there could be an accumulation of the active drug and a higher risk of side effects. A lower dosage of the medication may be required in poor metabolizers of an active drug.
- **Intermediate metabolizers.** People who break down a medication more slowly than normal, but not as slowly as a poor metabolizer. They will likely have similar effects as poor metabolizers but not as pronounced.
- **Extensive metabolizers.** People who metabolize medications normally.
- **Ultra-rapid metabolizers.** People who metabolize medications more quickly than average. In the case of active drugs they may metabolize the drug too quickly for it to work. They may need a higher dosage or a different

medication. In the case of prodrugs, they may produce too much of the active drug which can cause side effects or overdose.

Pharmacogenomic variants

The most common type of variant in a gene that affects our response to drugs is a single nucleotide polymorphism (SNP). A SNP involves a variation in a single base pair in a genetic sequence. Other types of genetic variants that can affect our response to different medications are:

- **Copy number variant (CNV).** Duplication of a piece of DNA sequence. This section can be duplicated many times. This often involves the duplication of a particular gene.
- **Insertions.** An additional piece of DNA inserted into a DNA sequence.
- **Deletions.** A piece missing from the DNA sequence.

Common pharmacogenomic genes

There are many genes which influence how our body metabolizes drugs and how they affect us. In 2021 there were about 100 variants in more than 900 genes that were known to affect response to medications. A number of these genes affect the metabolism of more than one drug. The three most common gene types included in pharmacogenomic tests are:

1. cytochrome P450s
2. VKORC1
3. TPMT

Cytochrome P450 (CYP)

Cytochrome P450 (CYP) gene variants are the most common variants associated with drug response. Variants in five of these genes: CYP2D6, CYP2C19, CYP2C9, CYP3A4 and CYP3A5 affect the drug response for approximately 70%–90% of currently available prescription drugs.

CYP2D6 is the most well known pharmacogenomic variant. More than 100 variants in this gene are known. Several of these variants result in inactive or absent protein. We each have two copies of each gene. People with a variant that decreases the activity of the CYP2D6 gene in both copies of their CYP2D6 gene, are poor metabolizers. About 5%–10% of white people are poor metabolizers. People with a variant in only one copy of this gene are normal metabolizers (extensive metabolizers). People with more than two copies of the CYP2D6 gene metabolize drugs more quickly and are called ultra-rapid metabolizers. Ultra-rapid metabolizers (UMs) have extremely high enzyme activity.

CYP2D6 gene variants affect most antidepressants, opioids, epilepsy drugs, and some heart medications. Commonly affected drugs are: tramadol, venlafaxine, morphine, mirtazapine, and metoprolol.

For example, ultra-rapid metabolizers with variations in the CYP2D6 turn codeine into morphine at a more rapid rate and make greater amounts of morphine. They are at greater risk for having an overdose if they use codeine or other opioids and having serious problems as a result. Breastfeeding mothers with this variation who use codeine, are at increased risk for providing excessive amounts of morphine to their baby. This can result in serious breathing problems in the infant and even death. Codeine does not work very well for poor metabolizers and they may need to use an alternative pain reliever.

The antidepressant drug amitriptyline is metabolized mainly by CYP2D6 and CYP2C19. People who are CYP2D6 ultra-rapid metabolizers have multiple copies of the gene. CYP2C19 ultra-rapid metabolizers possess

QUESTIONS TO ASK YOUR DOCTOR

- Is pharmacogenomic testing available for the drugs that I am taking?
- What are the limitations of pharmacogenomic testing?
- What pharmacogenomic test would you recommend?

variants in both copies of the gene that increase the function of this gene. People who are poor metabolizers have variants that produce non-functioning CYP2D6 or CYP2C19 proteins.

The Clinical Pharmacogenetics Implementation Consortium (CPIC) recommends that CYP2D6 and CYP2C19 ultra-rapid metabolizers do not take amitriptyline because it does not work very well for them. If this drug must be used in an CYP2D6 ultra-rapid metabolizer then a higher dose is recommended. CYP2D6 intermediate metabolizers should start with a 25% lower dose of amitriptyline. Poor CYP2D6 and CYP2C19 metabolizers should avoid the drug because of potential side effects. If a CYP2D6 or CYP2C19 poor metabolizer must take amitriptyline then a 50% reduced starting dose is recommended.

VKORC1

The vitamin K epoxide reductase complex subunit 1 gene (VKORC1) is the main gene which affects response to warfarin. Warfarin is the most commonly prescribed drug used to decrease blood clots in patients with strokes, blood clots and irregular heart beat etc. The VKORC1 gene is responsible for production of the VKOR protein. Warfarin works by inhibiting VKOR which reduces the conversion of vitamin K epoxide into vitamin K and decreases the formation of clotting factors.

Variants in CYP2C9 also affect warfarin metabolism. A dose reduction is recommended for individuals who are CYP2C9 poor and intermediate metabolizers or those who carry 2 copies of the variant VKORC1 A allele.

TPMT

Thiopurine methyltransferase (TPMT) is a protein that is involved in metabolizing a class of drugs called thiopurines. Thiopurines are used to treat leukemia, and autoimmune disorders like rheumatoid arthritis. Up to 14% of people have decreased activity of TPMT resulting from one of four TPMT gene variants. High levels of drug metabolites can accumulate in poor metabolizers. If they are treated with

standard doses of thiopurines they are at increased risk for serious side effects that can be fatal like decreased production of blood cells, gastrointestinal intolerance, inflammation of the pancreas and immune reactions. It is recommended that poor metabolizers start with a drastically reduced dose and then increase their dose gradually.

Phenylketonuria (PKU)

Definition

Phenylketonuria (PKU) is a rare metabolic disorder caused by a deficiency in the production of the hepatic (liver) enzyme phenylalanine hydroxylase (PAH). Phenylalanine hydroxylase deficiency describes a group of disorders that includes PKU. Other conditions described in this group are known as non-PKU hyperphenylalaninemia (non-PKU HPA) and variant PKU. PKU is the most serious form of the three diseases, all of which involve above-normal (elevated) levels of phenylalanine in the blood. The primary symptom of untreated PKU, intellectual disability, is the result of consuming foods that contain the amino acid phenylalanine, which is toxic to brain tissue.

PKU is an inherited, autosomal recessive disorder. It is the most common genetic disease involving amino acid metabolism. PKU is incurable, but early, effective treatment can prevent the development of serious mental incapacity.

Description

PKU is a disease caused by the liver's inability to produce the protein phenylalanine hydroxylase (PAH). This enzyme converts (metabolizes) the amino acid called phenylalanine into another amino acid, tyrosine. This is the only role of PAH in the body. A lack of PAH results in the build-up of abnormally high phenylalanine concentrations (or levels) in the blood and brain. Above-normal levels of phenylalanine are toxic to the cells that make up the nervous system and causes irreversible abnormalities in brain structure and function in PKU patients. Phenylalanine is a type of teratogen. Teratogens are any

Test strips used to screen for PKU. (Philippe Garo/Science Source)

substance or organism that can cause birth defects in a developing fetus.

PKU and the human nervous system

The extensive network of nerves in the brain and the rest of the nervous system are made up of nerve cells. Nerve cells have specialized extensions called dendrites and axons. Stimulating a nerve cell triggers nerve impulses, or signals, that slow down the axon. These nerve impulses then stimulate the end of an axon to release chemicals called neurotransmitters that spread out and communicate with the dendrites of neighboring nerve cells.

Many nerve cells have long, wire-like axons that are covered by an insulating layer called the myelin sheath. This covering helps speed nerve impulses along the axon. In untreated PKU patients, abnormally high phenylalanine levels in the blood and brain can produce nerve cells with abnormal axons and dendrites and cause imperfections in the myelin sheath referred to as hypomyelination and demyelination. This loss of myelin can “short circuit” nerve impulses (messages) and interrupt cell communication. A number of brain scan studies also indicate a degeneration of the white matter in the brains of older patients who have not maintained adequate dietary control.

PKU can also affect the production of one of the major neurotransmitters in the brain, called dopamine. The brain makes dopamine from the amino acid tyrosine. PKU patients who do not consume enough tyrosine cannot produce sufficient amounts of dopamine. Low dopamine levels in the brain disrupt normal communication between nerve cells, which results in impaired cognitive (mental) function.

Some preliminary research suggests that nerve cells of PKU patients also have difficulty absorbing tyrosine. This abnormality may explain why many PKU patients who receive sufficient dietary tyrosine still experience some form of learning disability.

Genetic profile

PKU symptoms are caused by alterations or mutations in the *PAH* gene, which is responsible for producing the enzyme phenylalanine hydroxylase. Mutations in the *PAH* gene prevent the liver from producing adequate levels of the PAH enzyme needed to break down phenylalanine. The *PAH* gene is found on chromosome 12 in the human genome. As of 2015, more than 500 different mutations had been identified in the *PAH* gene.

PKU is an autosomal recessive disorder. The term “autosomal” means that the gene for PKU is not located on either the X or Y sex chromosome, but rather on one of the numbered chromosomes. Everyone carries 46

chromosomes within their cells. Chromosomes contain genes, the blueprints for who we are and what we look like. Every person inherits 23 chromosomes from his or her mother and 23 from his or her father. The first 22 chromosomes are autosomes because they contain genes that are found in both males and females. The gender-specific chromosomes are XX for female and XY for male.

A person with one normal and one PKU gene mutation is called a carrier. A carrier does not display any symptoms of the disease because the liver produces normal quantities of the PAH enzyme. However, PKU carriers can pass the PKU genetic mutation on to their children. Two carrier parents have a 25% chance of producing a baby with PKU symptoms and a 50% chance of having a baby that is a carrier for the disease. Although PKU conforms to these basic genetic patterns of inheritance, the actual expression, or phenotype, of the disease is not strictly an “either/or” situation. This is because there are at least 500 different types of PKU mutations. Although some PKU mutations cause rather mild forms of the disease, others can initiate much more severe symptoms in untreated individuals. The more severe the PKU mutation, the greater the effect on cognitive development and performance (mental ability).

Also, it must be remembered that human cells contain two copies of each type of gene. Different combinations of any two PKU mutations tend to produce a wide spectrum of physiological and psychological symptoms. For example, patients who receive two “severe” PKU mutations from their parents can potentially develop more serious symptoms than people who possess a combination of one severe type and one milder form of mutation. To further complicate the genetic picture of PKU, other types of genes have been identified that seem to be responsible for the abnormal processing of phenylalanine in brain tissue. These abnormalities add to the severity of PKU symptoms experienced by patients who inherit these genes. In more detail, the association of multiple types of genes with a single condition, such as PKU, is referred to as molecular heterogeneity.

Demographics

One in 50 individuals of northern European origin are carriers for a PKU mutation. About 1 in 10,000 babies tests positive for PKU in the United States, but only one in a million babies is symptomatic with PKU due to the small number of infants who are not detected through carrier screening. Studies indicate that the incidence of this disease in northern European populations is higher than in African American, Eastern European, and Finnish populations.

KEY TERMS

Amino acids—Organic compounds that form the building blocks of protein. There are 20 types of amino acids (eight are “essential amino acids” that the body cannot make and that must be obtained from food).

Axon—Skinny, wire-like extension of nerve cells.

Enzyme—A protein that catalyzes a biochemical reaction or change without changing its own structure or function.

Gene—A building block of inheritance that contains the instructions for the production of a particular protein and is made up of a molecular sequence found on a section of DNA. Each gene is found on a precise location on a chromosome.

Genetic disease—A disease that is (partly or completely) the result of the abnormal function or expression of a gene; a disease caused by the inheritance and expression of a genetic mutation.

IQ—Abbreviation for Intelligence Quotient. Compares an individual’s mental age to his or her true or chronological age and multiplies that ratio by 100.

Metabolism—The total combination of all of the chemical processes that occur within the cells and tissues of a living body.

Mutation—An inherited or *de novo* change in the DNA sequence of the genome.

Myelin—A fatty sheath surrounding nerves in the peripheral nervous system that helps them conduct impulses more quickly.

Nervous system—The complete network of nerves, sense organs, and brain in the body.

Phenylalanine—An essential amino acid that must be obtained from food since the human body cannot manufacture it.

Protein—Important building blocks of the body, composed of amino acids, that are involved in the formation of body structures and control the basic functions of the human body.

Recessive—Refers to a genetic trait that is expressed only when present on both members of a pair of genes, one inherited from each parent.

Signs and symptoms

Untreated PKU patients develop a broad range of symptoms related to severely impaired cognitive function, sometimes referred to as intellectual disability.

Other symptoms can include extreme patterns of behavior, delayed speech development, seizures, a characteristic body odor, and light body pigmentation. The light pigmentation is due to a lack of melanin, which normally colors the hair, skin, and eyes. Melanin is made from the amino acid tyrosine, which is lacking in untreated cases of PKU. Physiologically, PKU patients show high levels of phenylalanine and low levels of tyrosine in the blood. Babies do not show any visible symptoms of the disease for the first few months of life. However, typical PKU symptoms usually do show up by a baby’s first birthday.

Diagnosis

The primary diagnostic test for PKU is the measurement of phenylalanine levels in a drop of blood taken from the heel of a newborn baby’s foot. PKU testing was introduced in the early 1960s and is the largest genetic screening program in the United States. It is required by law in all 50 states. Early diagnosis is critical. It ensures the early treatment PKU babies need to develop normally and avoid the complications of PKU.

The American Academy of Pediatrics recommends that this test be performed on infants between 24 hours and seven days after birth. The preferred time for testing is after the baby’s first feeding. Tandem mass spectrometry is terminology used to describe how newborn screening was performed as of 2015. This is a more accurate and fully automated analysis when compared to earlier newborn screening techniques. If the initial PKU test produces a positive result, then follow-up tests are performed to confirm the diagnosis and to determine if the elevated phenylalanine levels may be caused by some medical condition other than PKU. Treatment for PKU is recommended for babies who show a blood phenylalanine level of 7–10 mg/dL or higher for more than a few consecutive days. Another, more accurate test procedure for PKU measures the ratio (comparison) of the amount of phenylalanine to the amount of tyrosine in the blood.

To confirm a suspected diagnosis of PKU based on the newborn screening analysis, molecular genetic testing can be performed. Knowing the type of *PAH* mutation can help physicians with treatment decisions. For example, certain mutations will allow physicians to predict which infants will benefit from BH4 (tetrahydrobiopterin) supplementation.

Treatment and management

The severity of the PKU symptoms experienced by people with this disease is determined by both lifestyle and genetic factors. In the early 1950s, researchers first demonstrated that phenylalanine-restricted diets could eliminate most of the typical PKU symptoms—except

for intellectual disability. Dietary therapy (also called nutrition therapy) is the most common form of treatment for PKU patients. PKU patients who receive early and consistent dietary therapy can develop fairly normal mental capacity to within about five IQ points of their healthy peers. By comparison, untreated PKU patients generally have IQ scores below 50.

Infants with PKU should be put on a specialized diet as soon as they are diagnosed to avoid progressive brain damage and other problems caused by an accumulation of phenylalanine in the body. A PKU diet helps patients maintain very low blood levels of phenylalanine by restricting the intake of natural foods that contain this amino acid. Even breast milk is a problem for PKU babies. Special PKU dietary mixtures or formulas are usually obtained from medical clinics or pharmacies.

Phenylalanine is actually an essential amino acid. This means that it has to be obtained from food because the body cannot produce this substance on its own. Typical diets prescribed for PKU patients provide very small amounts of phenylalanine and higher quantities of other amino acids, including tyrosine. The amount of allowable phenylalanine can be increased slightly as a child becomes older.

In addition, PKU diets include all the nutrients normally required for good health and normal growth, such as carbohydrates, fats, vitamins, and minerals. High-protein foods like meat, fish, chicken, eggs, nuts, beans, milk, and other dairy products are banned from PKU diets. Small amounts of moderate-protein foods (such as grains and potatoes) and low-protein foods (some fruits and vegetables, low-protein breads and pastas) are allowed. Sugar-free foods, such as diet soda, which contain the artificial sweetener aspartame, are also prohibited foods for patients with PKU. This is because aspartame contains the amino acid phenylalanine.

Ideally, school-age children with PKU should be taught to assume responsibility for managing their diet, recording food intake, and performing simple blood tests to monitor their phenylalanine levels. Blood tests should be done in the early morning when phenylalanine levels are highest. Infants and young children require more frequent blood tests than older children and adults. The amount of natural foods allowed in a diet could be adjusted to ensure that the level of phenylalanine in the blood is kept within a safe range. Recommendations are for children under two to maintain their total phenylalanine intake to at least 3 g/kg/day and 25 mg of tyrosine/kg/day. For children older than two, the recommendation is to maintain their phenylalanine intake to 2 g/kg/day and 25 mg of tyrosine/kg/day.

A specialized PKU diet can cause abnormal fluctuations in tyrosine levels throughout the day. Thus, some health professionals recommend adding time-released tyrosine that can provide a more constant supply of this amino acid to the body. It should be noted that some PKU patients show signs of learning disabilities even with a special diet containing extra tyrosine. Research studies suggest that these patients may not be able to process tyrosine normally.

For PKU caregivers, providing a diet that is appealing as well as healthy and nutritious is a constant challenge. Many patients with PKU, especially teenagers, find it difficult to stick to the relatively bland PKU diet for extended periods of time. Some older patients decide to go off their diet plan simply because they feel healthy. However, many patients who abandon careful nutritional management develop cognitive problems, such as difficulties remembering, maintaining focus, and paying attention. Many PKU health professionals contend that all patients with PKU should adhere to a strictly controlled diet for life. The National Institutes of Health (NIH) recommends weekly monitoring of blood phenylalanine levels for the first year and then twice a week until age 13. After age 13, the NIH recommends monthly monitoring.

One promising line of PKU research involves the synthesis (manufacturing) of a new type of enzyme that can break down phenylalanine in food consumed by the patient. This medication would be taken orally and could prevent the absorption of digested phenylalanine into the patient's bloodstream.

In general, medical researchers express concern about the great variation in treatment programs currently available to PKU patients around the world. They have highlighted the urgent need for new, consistent international standards for proper management of PKU patients, which should emphasize comprehensive psychological as well as physiological monitoring and assessment.

PKU and pregnancy

Women with PKU must be especially careful with their diets if they want to have children. They should ensure that phenylalanine blood levels are under control before conception and throughout pregnancy. Mothers with elevated (higher than normal) phenylalanine levels are high risk for having babies with significant birth disorders, such as microencephaly (smaller than normal head size), congenital heart disease (abnormal heart structure and function), stunted growth, mental impairment, and psychomotor (coordination) difficulties. This condition is referred to as maternal PKU and can even affect babies who do not have the PKU disease.

QUESTIONS TO ASK YOUR DOCTOR

- How is phenylketonuria diagnosed?
- If I have phenylketonuria, what are the chances that any children I have will also contract the disorder?
- Are there any treatments other than diet control that I should consider to avoid complications associated with phenylketonuria?
- Can you recommend any books, pamphlets, brochures, or other material that provide further information about phenylketonuria?

Prognosis

Early newborn screening, careful monitoring, and life-long strict dietary management can help PKU patients to live normal, healthy, and long lives.

Pierre-Robin sequence

Definition

Pierre-Robin sequence consists of micrognathia (small lower jaw) or retrognathia (lower jaw displaced to the back), glossoptosis (displacement of the tongue into the throat), and obstruction of the airway. It is usually accompanied by a cleft palate (an opening in the roof of the mouth). The term "sequence" is used to describe the pattern of multiple anomalies derived from a single known prior anomaly or mechanical factor.

Description

Children who are born with Pierre-Robin sequence have small mandibles (lower jaws) or mandibles that are displaced back, tongues that are pushed back into the throat, and difficulty breathing of varying degrees. They also have difficulty feeding. Pierre-Robin sequence is usually accompanied by a cleft palate. Pierre-Robin sequence is more often associated with other types of hereditary disorders, most commonly Stickler syndrome and velocardiofacial syndrome. Pierre-Robin syndrome is also referred to as Robin sequence.

Genetic profile

Pierre-Robin sequence can occur in association with other syndromes, isolated (not associated with other malformations), or in association with other developmental disorders that do not represent a specific syndrome. Pierre-Robin sequence found in association with numerous syndromes may have a mode of inheritance that is related to the syndrome itself. The mode of inheritance includes single gene as well as chromosomal abnormalities.

Pierre-Robin sequence is usually not inherited, but when it is, it is inherited in an autosomal dominant pattern. This form of Pierre-Robin syndrome is due to a

genetic mutation of the *SOX9* gene, which is located on the long arm of chromosome 17. The *SOX9* gene codes for the development of the fetal skeleton and the fetal reproductive system and is also a transcription factor, regulating other genes.

Demographics

The incidence of Pierre-Robin sequence is reported to be one out of 8,500 to one out of 14,000 live births. This wide range is due to different diagnostic criteria and the presence or absence of associated syndromes. Less than 20%–40% of newborns born with Pierre-Robin sequence have the isolated type.

Signs and symptoms

In Pierre-Robin sequence, the lower jaw of the fetus displaces the tongue backward into the throat. The tongue located in this abnormal position blocks the embryonic structures from joining in the midline in order to form the palate, the roof of the mouth. The result is a cleft palate—an opening in the roof of the mouth. The size of the cleft palate varies, as does its position. It is not present in all patients.

Babies born with Pierre-Robin have difficulty feeding and breathing, because the tongue—pushed backward by the lower jaw—obstructs the throat. Feeding and breathing difficulties may be very mild or very severe.

Affected persons may also develop hearing problems due to fluid collecting in the ears.

Preconception Care

Maternal alcohol consumption is closely associated with alcohol-related birth defects and neurodevelopment. Hence, it is widely recommended for women to quit consuming alcohol before and during pregnancy. There is also evidence that paternal alcohol exposure biologically increases the risk of genetic and epigenetic sperm abnormalities. However, a recent study found that future fathers should be encouraged to modify their alcohol intake before conceiving, to reduce fetal risk, since a paternal drinking rate of 31% substantially elevated the risk of birth defects. This prospective, population-based study based was conducted in China and included couples who were planning a pregnancy within six months. Paternal alcohol consumption before conception was defined as at least one time drinking per week. Birth defects were reported by parents in the follow-up at 42 days after delivery. This study provided evidence for association of preconception paternal alcohol consumption with increased fetal birth defect risk and could have clinical implications for improving offspring life quality.

KEY TERMS

Endoscope—A slender, tubular optical instrument used as a viewing system for examining an inner part of the body. With an attached instrument, the endoscope can be used for biopsy or surgery.

Fibroid—A noncancerous tumor of connective tissue made of elongated, threadlike structures, or fibers, which usually grow slowly and are contained within an irregular shape. Fibroids are firm in consistency but may become painful if they start to break down or apply pressure to areas within the body. They frequently occur in the uterus and are generally left alone unless growing rapidly or causing other problems. Surgery is needed in order to remove fibroids.

Uterus—A muscular, hollow organ of the female reproductive tract. The uterus contains and nourishes the embryo and fetus from the time the fertilized egg is implanted until birth.

Diagnosis

Prenatal ultrasonic examination may show findings to indicate the possibility of Pierre-Robin sequence, alerting the physician to be prepared at birth for the possibility of the baby having breathing and feeding problems.

Treatment and management

The type of treatment varies according to the severity of the symptoms and their duration. Babies might not require any therapy if they have no symptoms of breathing difficulties and no feeding difficulties.

If breathing difficulties are mild, the easiest management is keeping the baby in the prone position, which causes the tongue to fall forward, relieving the obstruction. A thorough evaluation of these patients must be conducted, which includes endoscopy of the airways and upper digestive tract. Close monitoring must be maintained, because the prone position may obscure breathing difficulties.

If positioning the patient prone fails, a nasopharyngeal airway may be used, but only for a short time. The airway is a tube that the baby can breathe through, passed through the nose into the upper airway.

If the previously discussed methods fail or are required for a prolonged length of time, then some type of surgical intervention will be necessary. Surgical procedures include glossopepy, in which the tongue is sutured to the lower lip in order to prevent it from moving back

into the throat and causing obstruction. Subperiosteal release of the floor-of-the-mouth muscles on the lower jaw is an operation performed so that the tongue can no longer move back into the throat, because muscles are released from their insertions. Tracheotomy is performed by surgically cutting an opening in the trachea (wind-pipe). This opening bypasses the obstruction. The choice of surgical intervention varies according to the duration and severity of respiratory obstruction, other causes of respiratory obstruction that may be present, and the experience of the surgeon. Glossopexy and tracheotomy are temporary and reversed when the baby can breathe adequately on his or her own.

Another surgical procedure utilized for the treatment of Pierre-Robin sequence is known as Piezosurgery. This is a technique that uses ultrasound to cut bone, allowing for precise cutting and mandibular distraction to release the obstruction of the airway. It is the best technique currently available, due to its precision and low likelihood of damaging surrounding soft tissues of the head and neck.

The treatment of feeding difficulty varies according to its degree. It has been found that the severity of feeding difficulty is proportional to the severity of airway obstruction. Feeding is usually accomplished with a specialized cleft palate nipple and bottle or nasogastric tube (a feeding tube passed through the nose and into the stomach). Sometimes, a gastrostomy tube is needed for feeding. This is a tube passed through a surgical opening made in the abdominal wall and stomach.

Children with Pierre-Robin sequence are prone to hearing loss due to fluid collecting behind the tympanic membrane (eardrum); they may require drainage tubes placed into the ear.

If the child has a cleft palate, it is usually surgically repaired between the ages of nine and 18 months.

Prognosis

The prognosis for individuals with Pierre-Robin sequence varies with the severity of symptoms and depends on whether it is associated with other congenital abnormalities. The more severe the symptoms and associated congenital abnormalities, the greater the risk of complications. The mortality rate is about 30%.

The rate at which the lower jaw starts to catch up in growth depends on the cause of Pierre-Robin sequence. The majority of children with the isolated type will achieve near normal jaw size within a few years of birth. If Pierre-Robin sequence is part of a syndrome that has a small jaw, the jaw may remain small throughout life.

Poland anomaly

Definition

Poland anomaly (Poland syndrome) is a rare pattern of malformations present at birth that includes unilateral changes in the chest and shoulder girdle muscles, forearm bones, and fingers. Although there are other associated features, the most recognized characteristics are abnormalities of the major chest muscles (pectoralis) and the presence of syndactyly or webbing that joins the fingers of the hand. Treatment of this anomaly is mainly through reconstructive surgery.

Description

Poland anomaly (also known as Poland syndactyly, Poland syndrome, Poland sequence, or pectoral dysplasia-dysdactyly) was first described in 1841 by Alfred Poland, who was a medical student at Guy's Hospital in London when he noted malformations in the body of a deceased convict named George Elt. The diagnosis of Poland anomaly may encompass various combinations of the following abnormalities:

- absence of major chest muscles: pectoralis major, pectoralis minor
- hand anomalies: syndactyly (webbed or fused fingers), shortened fingers
- underdeveloped forearm bones: ulna, radius
- underdeveloped or absence of the nipple and, in females, the breast
- absence of groups of rib cartilage
- absence of shoulder girdle muscles: latissimus dorsi, serratus anterior
- underdeveloped skin and underlying tissue of the chest
- abnormal curvature of the spine
- patchy hair growth under the arm
- rare associations with abnormalities in the heart or kidney or development of certain cancers

In most cases, physical abnormalities are confined to one side of the body and tend to favor the right side by almost two to one. The manifestations of Poland anomaly are extremely variable, and rarely are all the features recognized in one individual. Involvement of the pectoralis muscle and fingers is the most consistent feature.

The exact cause of Poland anomaly is not known, but it may result from the interruption of fetal growth at about the forty-sixth day of pregnancy, when the fetal fingers and pectoralis muscle are developing. Several researchers have suggested that there may be too little blood flow through the fetal subclavian artery that goes to the chest and arm; the more severe the blood flow disruption, the more numerous and severe the resulting malformations. However, the final proof for this idea has not been found.

Genetic profile

Most occurrences of Poland anomaly appear to be sporadic (i.e., random and not associated with an inherited disorder) and are not passed from parent to child. However, there have been rare reports of Poland anomaly that appears in multiple members of the same family. In at least one case, this familial occurrence of Poland anomaly appears to be inherited in an autosomal dominant pattern. The fact that other organ systems (kidney, heart) and increased risks of certain cancers are associated with this condition supports

KEY TERMS

Autosomal dominant—A pattern of inheritance in which only one copy of a defective gene on a nonsex chromosome is required for a disease or inherited trait to develop in an individual.

Dextrocardia—Right-sided positioning of the heart.

Pectoralis muscles—Major muscles of the chest wall.

Renal agenesis—Complete absence of one or both kidneys.

Sporadic—Isolated or appearing occasionally with no apparent pattern.

Syndactyly—Webbing or fusion between the fingers or toes.

the hypothesis that there may be some genetic abnormality. It has been noted that deletions of some tumor suppressor genes on chromosome 11, including *HRASLS5*, *RARRES3*, *HRASLS2* and *PLA2G16*, that are involved in cell growth and differentiation through the RAS-mediated signaling pathway are associated with Poland anomaly.

Demographics

Poland anomaly is not common. It affects 1 child in 30,000. Geographically, estimates of the frequency range from 1 in 17,213 in Japanese schoolchildren to an average of 1 in 32,000 live births in British Columbia, with a low incidence—1 in 52,530—in Hungary. For reasons that are unclear, Poland anomaly is two to three times more frequent in boys than in girls.

Signs and symptoms

The manifestations of Poland anomaly are most often limited to physical manifestations. The degree to which this condition is disabling depends on which manifestations are present and their individual severity, but it most often relates to disabilities in the affected arm and hand. Upon rare occasions, Poland anomaly is associated with dextrocardia (the position of the heart is the mirror image of its normal position), renal agenesis (maldevelopment of the kidney), or cancers such as leukemia, leiomyosarcoma, and non-Hodgkin lymphoma. Intelligence is not impaired by Poland anomaly.

Diagnosis

The diagnosis of Poland anomaly relies on physical exam and radiographic evaluation, such as the use of

QUESTIONS TO ASK YOUR DOCTOR

- What are the most common signs and symptoms associated with Poland anomaly?
- What kinds of treatment are available for this disorder, and what risks are associated with these treatments?
- What factors are involved in developing a prognosis for a child born with Poland anomaly?
- What is the direction of current research, if any, on Poland anomaly?

x-rays or other imaging techniques to define abnormal or missing structures that are consistent with the criteria for Poland anomaly. In 2015 there was a research group in Italy that performed molecular diagnostic testing for brachydactyly type E (*HOXD13* gene).

Treatment and management

During early development and progressing until young adulthood, children with Poland anomaly should be educated and trained in behavioral and mechanical methods to adapt to their disabilities. This program is usually initiated and overseen by a team of healthcare professionals, including a pediatrician, physical therapist, and occupational therapist. A counselor specially trained to deal with issues of disabilities in children is often helpful in assessing problem areas and encouraging healthy development of self-esteem. Support groups and community organizations for people with Poland anomaly or other disabilities often prove useful as well.

After growth development is advanced enough (usually late adolescence or early adulthood), reconstructive plastic surgery may be offered, primarily to correct cosmetic appearance. The goal of reconstruction is to restore the natural contour of the chest wall while stabilizing the chest wall defect. Chest wall reconstruction must be tailored to the requirements of each patient, but it often involves moving and grafting ribs and muscles from other parts of the body to reconstruct the chest wall and breast. In addition, bioengineered cartilage or breast implants can be used to help give the chest a more normal appearance. Hand abnormalities are treated according to the severity and require individual consultation with a reconstructive plastic surgeon.

Prognosis

The prognosis for people with Poland anomaly is excellent. Reconstructive surgery is safe, and the

cosmetic corrections achieved can be significant. Associated symptoms of heart and kidney defects as well as cancer association are rare, but they indicate that patients with Poland anomaly should be followed closely by a physician familiar with the condition.

Polycystic kidney disease

Definition

Polycystic kidney disease (PKD) is one of the most common of all life-threatening human genetic disorders. It is an incurable genetic disorder characterized by the formation of fluid-filled cysts in the kidneys of affected individuals. These cysts multiply over time. It was originally believed that the cysts eventually caused kidney failure by crowding out the healthy kidney tissue. It is now thought that the kidney damage seen in PKD is actually the result of the body's immune system. The immune system, in its attempts to rid the kidney of the cysts,

Polycystic kidney disease: pedigree analysis chart (Gale)

instead progressively destroys the formerly healthy kidney tissue.

Description

A healthy kidney is about the same size as a human fist. PKD cysts, which can be as small as the head of a pin or as large as a grapefruit, can expand the kidneys until each one is bigger than a football and weighs as much as 38 lb. (17 kg).

There are two types of PKD: infantile PKD, which generally shows symptoms prior to birth; and adult-onset PKD. Individuals affected with infantile PKD are often stillborn. Among the liveborn individuals affected with infantile PKD, very few of these children survive to the age of two. The adult-onset form of PKD is much more common. The time and degree of symptom onset in the adult form of PKD can vary widely, even within a single family with two or more affected individuals. Symptoms of this form of PKD usually start to appear between the ages of 20 and 50. Organ deterioration progresses more slowly in adult-onset PKD than it does in the infantile form; but, if left untreated, adult-onset PKD also eventually leads to kidney failure.

Genetic profile

Polycystic kidney disease is expressed as both a recessive and a dominant trait. A recessive genetic trait will not cause disease in a child unless it is inherited from both parents. A dominant genetic trait can be inherited from just one parent. Those people affected with autosomal dominant PKD (ADPKD) have the much more common adult-onset form. Those with autosomal recessive PKD (ARPKD) have the infantile form.

There are mutations on at least three genes that cause adult-onset PKD. Approximately 85% of these cases are known to arise from mutations in the *PKD1* gene that has been mapped to a region on the short arm of chromosome 16 (16p13.3-p13.12). Another 10%–15% of cases of adult-onset PKD are thought to be caused by mutations in the *PKD2* gene that has been mapped to a region on the long arm of chromosome 4 (4q21-q23). It is thought that the remainder of the cases of PKD are caused by mutations in the *PKD3* gene, which has not yet been mapped. This unidentified “*PKD3* gene” may, in fact, be more than one gene.

Adult-onset PKD is transmitted from parents to their offspring as a non-sex-linked (autosomal) dominant trait. This means that if either parent carries this genetic mutation, there is a 50% chance that their child will inherit this disease. In the case of two affected parents, there is a 75% probability that their children will be affected with adult-onset PKD.

Infantile PKD is caused by a non-sex-linked (autosomal) recessive genetic mutation that has been mapped to a region on the short arm of chromosome 6 (6p21). Both parents must be carriers of this mutation for their children to be affected with infantile PKD. In the case of two carrier parents, the probability is 25% that their child will be affected by infantile PKD.

Demographics

One of the most common of all life-threatening genetic diseases, PKD affects about 500,000 in the United States alone. Over 12.5 million people worldwide are affected with PKD. Approximately one in

every 500 to 1,000 people is affected with ADPKD. Another one in 20,000 to 40,000 is affected with ARPKD. PKD is observed in both males and females. PKD is also observed with equal probability among ethnic groups.

Signs and symptoms

A baby born with infantile PKD has floppy, low-set ears, a pointed nose, a small chin, and folds of skin surrounding the eyes (epicanthal folds). Large, rigid masses can be felt on the backs of both thighs (flanks), and the baby usually has trouble breathing.

In the early stages of adult-onset PKD, many people show no symptoms. Generally, the first symptoms to develop are high blood pressure (hypertension); general fatigue; pain in the lower back or the backs of the thighs; headaches; and/or urinary tract infections accompanied by frequent urination.

As PKD becomes more advanced, the kidneys' inability to function properly becomes more pronounced. The cysts on the kidney may begin to rupture, and the kidneys tend to be much larger than normal. Individuals affected with PKD have a much higher rate of kidney stones than the rest of the population at this, and later stages, of the disease. Approximately 60% of those individuals affected with PKD develop cysts in the liver, while 10% develop cysts in the pancreas.

Because the kidneys are primarily responsible for cleaning the blood, individuals affected with PKD often have problems involving the circulatory system. These include an underproduction of red blood cells, which

PKD has made the kidney on the left substantially larger than the normal kidney on the right. (Jessica Wilson/Arthur Glauber/Science Source)

results in an insufficient supply of oxygen to the tissues and organs (anemia); an enlarged heart (cardiac hypertrophy), probably caused by long-term hypertension; and a leakage of the valve between the left chambers (auricle and ventricle) of the heart (mitral valve prolapse). Less common (affecting approximately 5% of PKD patients) are brain aneurysms. An aneurysm is an abnormal and localized bulging of the wall of a blood vessel. If an aneurysm within the brain leaks or bursts, it may cause a stroke or even death.

Other health problems associated with adult-onset PKD include chronic leg or back pain; frequent infections; and herniations of the groin and abdomen, including herniation of the colon (diverticular disease). A herniation, or hernia, is caused when a tissue,

Polycystic kidney disease: pedigree analysis chart (Gale)

KEY TERMS

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes.

Cancer—A disease caused by uncontrolled growth of the body's cells.

Computed tomography (CT) scan—An imaging procedure that produces a three-dimensional picture of organs or structures inside the body, such as the brain.

Cyst—An abnormal sac or closed cavity filled with liquid or semisolid matter.

Diuretics—Medications that increase the excretion of urine.

Kidney—Either of two organs in the lumbar region that filter the blood, excreting the end products of the body's metabolism in the form of urine and regulating the concentrations of hydrogen, sodium, potassium, phosphate, and other ions in the body.

Magnetic resonance imaging (MRI)—A technique that employs magnetic fields and radio waves to create detailed images of internal body structures and organs, including the brain.

Ultrasonogram—A procedure where high-frequency sound waves that cannot be heard by human ears are bounced off internal organs and tissues. These sound waves produce a pattern of echoes, which are then used by the computer to create sonograms or pictures of areas inside the body.

Uremic poisoning—Accumulation of waste products in the body.

designed to hold the shape of an underlying tissue, becomes weakened at a particular spot. The underlying tissue pushes against this weakened area until the area is no longer able to hold back the underlying tissue and the area forms an abnormal bulge through which the underlying tissue projects. Diverticular disease is caused by a weakening of the muscles that hold the shape of the organs of the digestive tract. These muscles weaken, allowing these organs, particularly one section of the colon, to form sac-like projections that can trap feces and become infected, or rupture.

In the final stages of PKD, the major symptom is kidney (renal) failure. Renal failure is indicated by an increase of nitrogen (in the form of urea) in the blood (uremia, or uremic poisoning). Uremia is a rapidly fatal condition without treatment.

Diagnosis

Many patients who have PKD do not have any symptoms. Their condition may not be discovered unless tests that detect it are performed for other reasons.

When symptoms of PKD are present, the diagnostic procedure begins with a family medical history and physical examination of the patient. If several family members have PKD, there is a strong likelihood that the patient has it too. If the disease is advanced, the doctor will be able to feel the patient's enlarged kidneys. Heart murmur, high blood pressure, and other signs of cardiac impairment can also be detected.

Urinalysis and a blood test called creatinine clearance can indicate how effectively the kidneys are functioning. Scanning procedures using intravenous dye reveal kidney enlargement or deformity and scarring caused by cysts. Ultrasound and computed tomography (CT) scans can reveal kidney enlargement and the cysts that caused it. CT scans can highlight cyst-damaged areas of the kidneys. A sampling of the kidney cells (biopsy) may be performed to verify the diagnosis.

Treatment and management

There is no way to prevent cysts from forming or becoming enlarged or to prevent PKD from progressing to kidney failure. Treatment goals include preserving healthy kidney tissue; controlling symptoms; and preventing infection and other complications.

If adult PKD is diagnosed before symptoms become evident, urinalysis and other diagnostic tests are performed at six-week intervals to monitor the patient's health status. If results indicate the presence of infection or another PKD-related health problem, aggressive antibiotic therapy is initiated to prevent inflammation that can accelerate disease progression; iron supplements or infusion of red blood cells are used to treat anemia; and surgery may be needed to drain cysts that bleed, cause pain, have become infected, or interfere with normal kidney function.

Lowering high blood pressure can slow loss of kidney function. Blood-pressure control, which is the cornerstone of PKD treatment, is difficult to achieve. Therapy may include antihypertensive medications, diuretic medications, and/or a low-salt diet. As kidney function declines, some patients need dialysis and/or a kidney transplant.

There is no known way to prevent PKD, but certain lifestyle modifications can help control symptoms. People who have PKD should not drink heavily or smoke. They should not use aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), or other prescription or over-the-counter medications that can impair kidney function. Individuals affected with PKD should eat a

QUESTIONS TO ASK YOUR DOCTOR

- What is the process by which polycystic kidney disease damages the human body?
- What is the genetic basis for this disorder?
- Are there treatments available that will extend the lifespan of a child diagnosed with polycystic kidney disease?
- What is the prognosis for a child with this condition?

balanced diet, exercise regularly, and maintain a weight appropriate for their height, age, and body type. Regular medical monitoring is also recommended.

Prognosis

There is no known cure for PKD. Those affected with infantile PKD generally die before the age of two. In adults, untreated disease can be rapidly fatal or continue to progress slowly, even after symptoms of kidney failure appear. About half of all adults with PKD also develop kidney failure. Unless the patient undergoes dialysis or has a kidney transplant, they usually do not survive more than four years after diagnosis.

Although medical treatment can temporarily alleviate symptoms of PKD, the expanding cysts continue to increase pressure on the kidneys. Kidney failure and uremic poisoning (accumulation of waste products the body is unable to eliminate) generally cause death about ten years after symptoms first appear.

Medications used to fight cancer and reduce elevated cholesterol levels have slowed the advance of PKD in laboratory animals. They may soon be used to treat adults and children who have the disease. Researchers are also evaluating the potential benefits of anti-inflammatory drugs, which may prevent the scarring that destroys kidney function.

Polycystic ovary syndrome

Definition

Polycystic ovary syndrome (PCOS), formerly Stein-Leventhal syndrome, is a disorder in which women do not experience normal release of eggs from the ovaries, they have an abnormal production of male hormones, and their body is resistant to the effects of the hormone insulin. The disorder results in infertility, abnormal masculinization, and increased risk of developing heart disease and certain cancers.

Description

The normal function of the female reproductive system is complex, requiring the interplay of different organ systems. One set of important organs are the ovaries. The ovaries are two small structures contained in the lower abdomen, on either side of the uterus, that contain small immature eggs called ova. Ova are stored within the ovaries in individual structures called follicles.

In a monthly cycle, a part of the brain called the pituitary gland secretes two substances into the bloodstream—luteinizing hormone (LH) and follicle-stimulating hormone (FSH). As certain levels of LH and FSH build in the bloodstream, the follicles of the eggs begin to swell and grow, creating a maturing follicle that eventually ejects an oocyte. Eventually, the changing levels of LH and FSH cause one of the ovarian follicles to burst open, releasing a mature egg. This process by which an egg is released from the ovary is called ovulation.

False-color scanning electron micrograph of a polycystic ovary, showing several cystic follicles protruding from the wall of the ovary. (Pietro M. Motta/Sayoko Makabe/Science Source)

Once a mature egg is released from the ovary, it passes into the fallopian tubes, tube-like structures that are passageways to the uterus. If sperm cells from the male are present within the fallopian tubes, they will join with the egg in a process called fertilization. The fertilized egg can then pass into the uterus and implant into the thickened wall of the uterus where it can develop into a fetus. If no sperm cells are present, the mature egg goes unfertilized and is lost, along with the thickened layer of the uterus, in a monthly process called menstruation.

Polycystic ovary syndrome (PCOS), first described by I. F. Stein and M. L. Leventhal in 1935, is a disorder in which normal ovulation does not occur. The term “polycystic” derives from the fact that the egg-containing cysts in the ovaries do not burst open, resulting in enlarged ovaries containing many swelled cysts. The reason for this problem in ovulation is unclear; however, several abnormalities have been characterized in women with PCOS. First, there is a disturbance in the production of LH and FSH by the pituitary, leading to altered levels of the substances in the bloodstream. There is also evidence that the ovaries do not respond appropriately to the FH and LSH that is present. Second, there is an abnormal overproduction of male hormones, called androgens, by the ovaries and the adrenal gland. Finally, women with PCOS are resistant to the effects of the hormone insulin. Insulin is a hormone made in the pancreas that is responsible for transport of sugar from the blood into the cells. While these abnormalities have been well characterized, it is unclear whether they cause PCOS or whether they are a result of the disease.

Genetic profile

Women diagnosed with PCOS frequently have relatives with symptoms similar to that seen in the disorder. As a result of these observations, many scientists have proposed that genetic factors play a role in the disease. Over the past few decades, researchers have identified families in which PCOS appears to be inherited with an autosomal dominant or an X-linked pattern. However, these cases are rare and do not hold true for the majority of people with PCOS.

Current theories suggest that different genetic changes may result in PCOS or that multiple genetic factors are needed for the full manifestation of the disease. Abnormalities in several genes have been associated with PCOS, including mutations in the genes for follistatin (locus 5p14), 17-beta-hydroxysteroid dehydrogenase (locus 9p22), and a cytochrome P450 enzyme (locus 15q23-q24). Each of these genes plays a different role in the response to LH and FSH, or in the conversion of male hormones to female hormones, although their relationship to PCOS is unclear. Ongoing research is likely to identify further genetic mutations that are associated with PCOS.

Demographics

Estimates of the prevalence of PCOS in the general population have ranged from 2%–20%, with recent studies suggesting that 5%–10% of women of reproductive age are affected by the disorder. This makes PCOS one of the most common hormone disorders in women of reproductive age. Thirty percent of women show some symptoms of PCOS. The overall prevalence rate of PCOS is about one in 40 women.

It is unclear whether this disease is distributed uniformly among different geographical areas and ethnic groups. However, studies performed in 1999 show the prevalence of this disorder in the United States is just over 3% in African-American females and almost 5% in Caucasian females. The prevalence of PCOS in Greek women was shown to be higher, at nearly 7%.

Signs and symptoms

The first signs of PCOS tend to manifest at puberty. As a result of the failure to ovulate normally, young women with PCOS may fail to menstruate or menstruate only erratically. A small percentage of women may have normal menstrual cycles. Women affected with PCOS often experience infertility, an inability to become pregnant. Additionally, women with PCOS tend to gain weight, and 70% eventually become obese.

KEY TERMS

Acanthosis nigricans—A skin condition characterized by darkly pigmented areas of velvety wart-like growths. Acanthosis nigricans usually affects the skin of the armpits, neck, and groin.

Androgens—A group of steroid hormones that stimulate the development of male sex organs and male secondary sexual characteristics.

Diabetes—An inability to control the levels of sugar in the blood due to an abnormality in the production of, or response to, the hormone insulin.

Fallopian tube—Either of a pair of tubes that conduct ova from the ovaries to the uterus.

Follicle—A pouch-like depression.

Follicle-stimulating hormone (FSH)—A hormone that stimulates estrogen in females and sperm production in males.

Hirsutism—The presence of coarse hair on the face, chest, upper back, or abdomen in a female as a result of excessive androgen production.

Hormone—A chemical messenger produced by the body that is involved in regulating specific bodily functions such as growth, development, and reproduction.

Infertility—Inability in a woman to become pregnant.

Insulin—A hormone produced by the pancreas that is secreted into the bloodstream and regulates blood sugar levels.

Luteinizing hormone (LH)—A hormone secreted by the pituitary gland that regulates the menstrual cycle

and triggers ovulation in females. In males it stimulates the testes to produce testosterone.

Masculinization—Development of excess body and facial hair, deepening of the voice, and increase in muscle bulk in a female due to a hormone disorder.

Menstruation—Discharge of blood and fragments of the uterine wall from the vagina in a monthly cycle in the absence of pregnancy.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and can be transmitted to offspring.

Ova—Another name for the egg cells that are located in the ovaries.

Ovary—The female reproductive organ that produces the reproductive cell (ovum) and female hormones.

Ovulation—The monthly process by which an ovarian follicle or cyst ruptures, releasing a mature egg cell.

Pituitary gland—A small gland at the base of the brain responsible for releasing many hormones, including luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

Uterus—A muscular, hollow organ of the female reproductive tract. The uterus contains and nourishes the embryo and fetus from the time the fertilized egg is implanted until birth.

The overproduction of androgens leads to changes in the body that are more typical of male development. For example, approximately 70% of women with PCOS will show hair growth on the face, chest, stomach, and thighs (hirsutism). Simultaneously, they show thinning of the hair more typical of male-pattern baldness. Other male characteristics, such as a deep voice, acne, and increased sex drive, may also be present, and affected women often have decreased breast size.

Women with PCOS do not respond appropriately to insulin. As a result, 15% of women with PCOS may develop high levels of sugar in the blood later in life, a condition known as diabetes. Resistance to insulin is also associated with dark, warty skin growths in the groin and armpits, known as acanthosis nigricans.

Untreated PCOS is a risk factor for the development of several dangerous conditions. The hormone abnormalities

in PCOS place women at considerable risk for endometrial cancer and possibly breast cancer. The risk of endometrial cancer is three times higher in women with PCOS than in normal women, and small studies suggest that the risk of breast cancer may be three to four times higher. PCOS also results in increased risk of high blood pressure, diabetes, and high cholesterol, all of which contribute to heart disease and stroke.

Diagnosis

A diagnostic search for PCOS is usually initiated when women experience an absence of menstrual periods for at least six months, an inability to become pregnant, and/or abnormal hair growth or acne. A comprehensive physical exam performed at that time may reveal excessive body hair, low voice, acanthosis nigricans, or

obesity. Enlarged ovaries are also identifiable on pelvic examination in about 50% of patients.

Blood tests can be performed that may yield results consistent with PCOS, including abnormal levels of LH and FSH (typically in a ratio of 3:1), abnormally high levels of androgens (testosterone, DHEA, DHEAS), abnormally high levels of insulin, and abnormally low levels of a substance called sex hormone-binding globulin. In addition, a physician may perform a diagnostic test called a progesterone challenge. In this test, a physician administers a hormone called progesterone to the patient to determine if it will provoke menstruation. If menstruation does occur in response to the progesterone, it is likely that a patient has PCOS.

Finally, an ultrasound examination of the ovaries may be performed to determine if large cystic follicles can be documented. With this approach, the diagnosis of PCOS is based on the finding of more than eight enlarged follicles in the ovary.

Treatment and management

There is no cure for PCOS, thus treatment focuses on several goals, including the restoration of the menstrual cycle, blocking the effect of androgens, reducing insulin resistance, lowering the risk of cancer and heart disease, and possibly restoring ovulation and fertility.

In patients who do not desire pregnancy, hormones can be administered in the form of birth control pills, which may result in normal menstrual cycles, decreased hair growth and acne, and a lower risk of developing endometrial cancer. Although women will note a decrease in hair growth after approximately six months of treatment with birth control pills, additional cosmetic hair removal therapy is often necessary. In women who do not respond appropriately to birth control pills, another medication known as leuprolide (Lupron) can be used, but with more long-term side effects (e.g., hot flashes, bone demineralization, atrophic vaginitis).

Other types of medication can be used to block the effects of androgens. When these medications are taken with birth control pills, 75% of women report decreased body hair growth. The most commonly used medications to block androgen effects are spironolactone (Aldactone), flutamide (Eulexin), and cyproterone (Cyprostat).

Treatment with medications that restore the body's normal response to insulin has been shown to decrease LH and androgen levels. Recent studies have demonstrated that such agents restore the menstrual cycle in 68%–95% of patients treated for as short a time as four to six months. One of the most commonly used medications to improve the effects of insulin is metformin (Glucophage).

QUESTIONS TO ASK YOUR DOCTOR

- How common is polycystic ovary syndrome in the general public?
- What medical conditions are associated with this disorder?
- How is polycystic ovary syndrome treated, and how effective are those treatments?
- Can you recommend an Internet site or two that will provide additional information on this condition?

In patients who are trying to become pregnant, a physician can administer medications that will cause ovulation. The main medication used to induce ovulation is clomiphene citrate (Clomid). Ovulation is successful in approximately 75% of women treated with clomiphene, but only 30%–40% of women will successfully become pregnant. Another medication, follitropin alpha (Gonal-F), has achieved pregnancy rates of 58%–82%, but may cause more side effects and frequently results in more than one baby per pregnancy.

Some women who do not respond to medications may undergo surgery to remove portions of the ovary. For reasons that are not completely understood, removal of a portion of the ovary may result in some degree of normal menstrual cycles.

While medications and surgery may provide a degree of symptomatic relief for some women, other simultaneous strategies can increase their benefits. Behavior modifications, including weight reduction, diet, and exercise, are recommended for all women with PCOS. As little as a 7% reduction in body weight can lead to a significant decrease in androgen levels and to the resumption of ovulation in obese women with PCOS. Cosmetic techniques, including electrolysis (destruction of the hair follicle using electricity) and laser therapy, may be used to decrease hair growth. Finally, women should be seen regularly for full physical examinations including pelvic exams to aid in the early detection of ovarian, breast, and uterine cancer and should be managed by an interdisciplinary health care team including a primary care physician, obstetrician/gynecologist, and reproductive endocrinologist.

Prognosis

While PCOS is one of the most common hormone disorders in young women, proper diagnosis and

treatment has greatly increased the quality of life in these individuals. Roughly half of women with PCOS will be able to achieve pregnancy, and about three-quarters will see reduction in masculine traits such as hair growth with proper medical treatment. Initiation of vigorous exercise and a restricted diet may result in even better outcomes. Patients with PCOS are at higher risk of developing diabetes, heart disease, and certain cancers and should be seen regularly by a physician. Barring these developments, lifespan in patients with PCOS is approximately the same as the general population.

Polydactyly

Definition

Polydactyly is the presence of extra fingers and toes (digits) at birth. Rather than having five fingers per hand or five toes per foot, an infant with polydactyly will have six or more digits on either the hands or feet that may or may not be fully formed.

Description

Polydactyly, also called supernumerary digits or extra digits, can occur on either the hands or feet, and the extent of the digit development is variable. Individuals with polydactyly can have one small extra rudimentary finger or toe on one of their hands or feet or they can

X-ray of a child's foot showing polydactyly; in this case, there are seven toes on the foot. (Zephyr/Science Source)

have fully formed extra digits on both their hands and feet. Extra digits can be fully formed or rudimentary and may contain no bones at all. Rudimentary digits may only be attached by a thin stalk of skin. Individuals are described as having isolated polydactyly if they only have extra digits and have no other obvious malformations. Most of the time, polydactyly occurs as an isolated condition, but it can occur as a symptom of different genetic syndromes. There are more than 100 different genetic syndromes that have polydactyly as one of their findings.

Different experts have different systems for describing polydactyly. The two most common systems describe the location and extent of the polydactyly. "Preaxial," "central," and "postaxial" are the terms used to describe the location of the extra digit. If the extra digit is located on the side of the hand by the thumb or on the side of the foot by the big toe, then a person is diagnosed with preaxial polydactyly. Postaxial polydactyly occurs when the extra digit is located on the side of the hand or foot by the fifth digit (the pinky or small toe), and central polydactyly occurs when the extra digit is located in between the thumb and pinky or between the big and little toes.

Type A and type B are used to describe the variable size of the digits in polydactyly. Extra digits can be fully formed with the right number of joints and bones, or they

KEY TERMS

Central polydactyly—Occurring between the thumb and little finger or between the big toe and the little toe.

Digit—A finger or a toe.

Dominant trait—A pattern of inheritance that involves genes that are located on autosomes (not sex chromosomes). In autosomal dominant inheritance, only one copy of a particular form of a gene is needed in order to show that trait.

Postaxial polydactyly—Occurring near the little finger (pinky) or the little toe.

Preaxial polydactyly—Occurring near the thumb or the big toe.

can be poorly formed with the wrong number of joints and no bones (rudimentary digits). Fully formed digits are type A polydactyly, and poorly formed or rudimentary digits are type B polydactyly. Thus, a person with a small rudimentary digit on the outside of the pinky is diagnosed with isolated postaxial polydactyly type B.

Genetic profile

Polydactyly is caused by errors that occur during the process of fetal development. There are a number of genes that determine the pattern of hands and feet. Some of these genes include *SHH*, *ZIC*, and *GLI3*, all of which have a direct connection to polydactyly when mutated, as seen in animal studies, as well as any disruption to the apical embryological ridge, which is important in the timing of growth and development. Many genes must be transcribed and translated correctly for growth and development to occur correctly, hence the incompleteness of the genetic model of polydactyly. Knockout studies in animals have been successful, however, in determining the role of many of these genes. There is strong evidence that the *GLI3* gene is the primary gene involved in polydactyly. This gene is located on the short arm of chromosome 7, and other genes involved in some manner are typically located on chromosome 13.

The three different types of polydactyly—postaxial, central, and preaxial—appear to have different patterns of inheritance. Postaxial polydactyly is inherited as an autosomal dominant that shows variable expressivity. The inheritance patterns for postaxial and central polydactyly are not well understood.

Genes are made of deoxyribonucleic acid (DNA) and located on chromosomes. DNA is composed of four units

(called bases) that are designated A, T, G, and C, named according to the nucleobase they represent. The sequence of the bases contains the instructions for making each of the body's structures. A change in one of the DNA letters making up a gene is a mutation. In some cases, mutations can alter the instructions and lead to malformations.

All individuals pass their chromosomes on to their children and, therefore, pass down their DNA instructions (genes). Genes always come in pairs: one pair each from the mother and one from the father. In an autosomal dominant disorder, only one gene needs to be altered for an individual to have the disorder or malformation. If an individual has the gene change (mutation) that causes postaxial polydactyly, there is a 50% chance that the disorder will be passed on to an offspring.

While the gene for polydactyly is passed unchanged from generation to generation, it often manifests itself very differently in different individuals. For example, a father may have the gene for polydactyly and have had a very small nubbin of soft skin on the outer edge of his hand. However, his child with the same gene may have extra fully formed digits on both hands and feet. This difference in how the gene manifests is called variable expression. The causes of variable expression are not well understood.

Most polydactyly occurs as an isolated condition. However, it can occur as one symptom of other more complicated genetic conditions. Some of the syndromes that polydactyly is a feature of are trisomy 13 syndrome, Meckel-Gruber syndrome, Bardet-Biedl syndrome, and Ellis-van Creveld syndrome.

Trisomy 13 is a rare, usually lethal, genetic syndrome caused by an extra number 13 chromosome. Infants with trisomy 13 have poor growth and multiple birth defects, including cleft lip, heart defects, and defects of the abdominal wall. This syndrome is usually diagnosed at birth.

Meckel-Gruber syndrome is an autosomal recessive syndrome characterized by poor growth, encephalocele (opening on the spine), postaxial polydactyly, and cystic kidneys. This syndrome is usually diagnosed at birth.

Bardet-Biedl is a rare autosomal recessive genetic syndrome characterized by obesity, postaxial polydactyly, retina (eye) abnormalities, and intellectual disability. Often, individuals with this syndrome are not diagnosed until childhood.

Ellis-van Creveld syndrome is a rare autosomal recessive genetic syndrome common in the Amish population. Infants with this syndrome have skeletal abnormalities, short arms and legs, and polydactyly. About half of these infants also have a heart defect. Most infants

with this syndrome are diagnosed shortly after birth or in infancy.

A 2015 study reported an extreme case of polydactyly that researchers named radial polydactyly. In this case study, duplication of many bones in the forearm, wrist, and hand were present on the radial side (thumb side). This study concluded that radial polydactyly should be included in the classification of types of polydactyly.

Demographics

Polydactyly is a relatively common birth defect that occurs in all ethnic groups. Postaxial polydactyly is the most common form of polydactyly and accounts for about 80% of cases. It occurs in about 1 in 2,000 Caucasian births and is about ten times more common in individuals with African ancestry. In about 30% of cases of polydactyly, there is a positive family history, and about 50% of polydactyly is bilateral (affects both sides of the body). Preaxial polydactyly is the most common form of polydactyly in individuals of Asian ancestry.

Signs and symptoms

The presence of polydactyly is most often noted at birth. While it can be shocking for some parents, the presence of isolated polydactyly poses no immediate health risks for the infant. It is a very common malformation that is easily treated by surgical removal.

Individuals with polydactyly can have one small extra rudimentary finger or toe on one of their hands or feet or they can have fully formed extra digits on both their hands and feet. Extra digits can be fully formed or rudimentary and may contain no bones at all. Rudimentary digits may only be attached by a thin stalk of skin.

Diagnosis

The diagnosis of polydactyly is usually made shortly after birth by physical examination. It can also be diagnosed prenatally or before a baby is born. Polydactyly can sometimes be seen on a prenatal ultrasound (sonogram) as early as 18 weeks gestation. If polydactyly is noticed on a sonogram, other medical tests may be suggested to make sure that the fetus does not have any of the problems associated with other genetic syndromes. A detailed sonogram should be done to measure the limbs and growth of the baby, while an amniocentesis may be offered to do a chromosomal analysis of the fetus. A fetal echocardiograph (heart ultrasound) may be performed to rule out heart abnormalities. In addition, other tests may be done to rule out other syndromes.

QUESTIONS TO ASK YOUR DOCTOR

- Is this the only genetic malformation my child has?
- Is surgery an option and, if so, how will it be performed?
- What is the best age for surgery to be performed on my child?
- What is the likelihood that my future children will have this type of growth abnormality?
- What will daily life be like if we do not perform surgery?

Treatment and management

When polydactyly is noted in an infant, a number of the following tests may be done.

- A very thorough medical examination to make sure that there are no other birth defects or abnormalities
- A medical family history to determine if anyone else in the family has had polydactyly or any other syndromes associated with polydactyly
- X-rays to determine the extent of the polydactyly (i.e., whether the digit contains bone or is just skin)
- Laboratory tests, such as chromosome analysis, enzyme assays, and further x-rays to determine that a suspected disorder is present.

While the initial diagnosis may be shocking to most parents, isolated polydactyly has no health consequences and is usually surgically corrected before the infant leaves the hospital.

Polydactyly is rarely a functional concern, and the removal of the extra digit is often for cosmetic purposes or to aid in the wearing of shoes. The age at which surgery is performed depends on the extent and degree of the polydactyly. A type B, or partially formed, digit that contains no bone may be removed before the infant leaves the hospital. A type A polydactyly is often corrected when the patient is one year of age.

Complex polydactyly (central polydactyly) may require multiple surgeries to improve function and cosmetic appearance.

Surgery is often successful, but in some cases the remaining digit may be smaller in size or slightly weaker in musculature, depending on the structure and placement of the additional digit. In this case, post-surgical physical

therapy and/or occupational therapy may be necessary during adolescence.

Prognosis

The prognosis for isolated polydactyly is excellent. When polydactyly is associated with another genetic syndrome, the prognosis is dependent on the presence of other features of that syndrome. Many of the genetic syndromes that have polydactyly as one of their symptoms are quite serious, and early death and significant disability are possibilities.

Polygenic risk scoring

Definition

Polygenic risk scoring (PRS) is a recently devised technique for estimating the total effect of many DNA variants on an individual's observable characteristics (phenotype) in order to determine his or her genetic predisposition for a given trait—most often, the risk of developing a complex disease. Another way of defining PRS is that it collects or compiles data from an individual's germline genome into a single number

proportional to the risk for a given disease. PRS is also known as a polygenic score (PGS), genetic risk score, or genome-wide score.

Purpose

PRS is currently used to assess a person's risk of developing complex diseases that cannot be predicted in the same way as Mendelian or single-gene diseases. Complex diseases are also called polygenic because they are influenced by a number of different genes for a specific trait, or multifactorial because they result from interactions between a person's genes and environmental factors. Because complex diseases such as heart disorders, stroke, and Alzheimer's disease are much more common in the general population than single-gene disorders like Huntington's disease or hemophilia, the development of risk profiles that could be used to advise people before they begin to show symptoms of a complex disease would be a major advance in improving population health.

Description

PRS was made possible by the introduction and publication of genome-wide association studies, or GWAS, in the early 2000s for such complex diseases as diabetes, coronary artery disease (CAD), and breast cancer. GWAS, also known as whole-genome association study or WGAS, differs from previous methods of genetic research in that it does *not* begin with candidate genes that are tested to see whether they are associated with the disease in question. Instead, GWAS researchers scan the complete genomes of many different subjects looking for single nucleotide polymorphisms (SNPs) that may be genetic markers of the disease. SNPs are variations in a genome involving a single base pair (two complementary nucleotides bonded together by hydrogen to form a unit within the double-helix structure of DNA). Most SNPs do not have a significant effect on health; however, others are located in portions of the human genome where they influence a person's risk of developing a complex disease even though they do not lie on the same chromosome.

In order to carry out a GWAS, researchers select two large groups of human subjects: a group of people diagnosed with the disease under investigation, and a group of controls (people who do not have the disease). Samples of DNA are collected from each subject and analyzed using SNP microarrays. If one SNP variant (one allele) is more common in the subjects diagnosed with the disease than in the control subjects, the SNP is said to be associated with the disease. The researchers then assign a statistical weight to each SNP to estimate its effect on total disease risk. There are several different

methods of statistical analysis that are currently used to refine the accuracy of the estimate; some involve machine learning, which involves computer algorithms that improve with use and the addition of new data.

Between 2008 and 2010, scientists began to expand GWAS by compiling many genomic variants associated with a disease into what is termed a polygenic score. While these early polygenic scores did improve the accuracy of disease risk prediction, physicians in clinical practice did not find these scores useful in advising or treating patients. Three developments led to a major change in polygenic risk scoring: 1) larger GWAS sample sizes, which led to more precise estimates of the effects of SNPs taken as a group; 2) algorithms that allowed researchers to combine sets of variants from across the genome; and 3) the availability of large biobanks that allow scientists to test their findings in a population group different from the one from which they recruited their subjects and controls.

Biobanks are large collections of samples of human blood and other biological specimens stored for use by qualified researchers. The biobank that was first used in polygenic risk scoring is the UK Biobank in Manchester, England, with its participant resource center in Cardiff, Wales. The UK Biobank contains over 500,000 biosamples, most of them taken from healthy British citizens. The scientists at the Broad Institute in Massachusetts who published a groundbreaking paper on PRS in 2018 derived their initial risk scores from GWAS studies of American subjects, primarily of European background. The Broad Institute team then used UK Biobank samples to validate the American data and calculations.

The first complex diseases that were investigated in 2018 include CAD, atrial fibrillation (an abnormal heart rhythm), type 2 diabetes, breast cancer, and inflammatory bowel disease (IBD). Subsequent PRS studies have looked at obesity, type 1 diabetes, schizophrenia, Alzheimer's disease, prostate cancer, malignant melanoma, basal cell carcinoma, hypothyroidism, high blood cholesterol levels, high blood pressure, asthma, gallstones, and glaucoma. One advantage of polygenic risk scoring for these and other complex disorders is that PRS can be assessed at the time of a person's birth, long before the symptoms that physicians use to evaluate a person's risk of CAD or other diseases begin to appear. In theory, finding a person's risk score early in life would allow intensive long-term preventive measures.

Limitations

The Broad Institute researchers noted that one major limitation of most GWAS in recent years is the overrepresentation of data derived from subjects of European

heritage. According to the National Human Genome Research Institute (NHGRI), 78% of the data used in current polygenic risk scoring is derived from people with European ancestry; 10% of the data is derived from Asians, 2% from Africans, and 1% from Hispanics, while the ancestry of the subjects who supplied 8.5% of the data is unreported. This disproportion means that current polygenic risk scores are most accurate for people of European ancestry but may be much less useful in estimating disease risk for individuals from other ethnic or racial groups. This situation is changing, however. In early 2021, the American College of Cardiology and the American Heart Association announced the validation of an integrated risk tool for predicting the 10-year risk of cardiovascular disease in persons of African American, Black African, Black Caribbean, Pakistani, Bangladeshi, or Indian ethnicities.

Another limitation of the PRS studies published to date is inconsistency in score reporting, which results from differences in study populations; the scientists' reasons for choosing those populations; statistical methods for interpreting the data; and transparency of reporting. In order to speed up the application of polygenic risk scoring to clinical use by standardizing reports, the Clinical Genome Resource (ClinGen) Complex Disease Working Group (an international group of researchers and clinicians funded primarily by NHGRI) and the Polygenic Score (PGS) Catalog (a resource supported by British and Australian public health authorities) drew up a list of 22 items to improve consistency in publishing PRS studies. The new reporting framework was published in *Nature* on March 10, 2021.

Another limitation of PRS is that it provides information only about relative, rather than absolute, risks of developing a disease. A person could be placed at the upper end of a PRS score distribution and never develop the disease in question. Conversely, someone at the low-risk end of the bell-shaped curve could still develop the disease. In addition, PRS poses ethical questions about the psychological impact of a high risk score on the patient receiving it. The usefulness of the information and the possible harm to the recipient are real difficulties for adult-onset disorders like Alzheimer's disease that currently have no effective preventive measures and no cure. At the very least, the physician would have to carefully explain the difference between relative and absolute risk to the patient.

Future applications

Polygenic risk scoring is not yet ready for general clinical use. While researchers hope that PRS can be used at some point to identify those at highest risk of a complex disease, evaluate the benefits of various preventive

KEY TERMS

Algorithm—A set of rules for solving a problem in a finite number of steps.

Allele—One of two (or more) forms of the same gene at the same place on a chromosome.

Atrial fibrillation—An abnormal heart rhythm characterized by the rapid and irregular beating of the two upper chambers (atria) of the heart.

Base pair (bp)—Any of the complementary nucleotide bases (adenine-thymine and cytosine-guanine in DNA; adenine-uracil and cytosine-guanine in RNA) held together by weak hydrogen bonds. Base pairs form links between the two strands of DNA.

Biobank—A repository of biological samples (usually human samples) for use in research.

Genome—The total amount of genetic information within an organism's chromosomes, including its genes and DNA sequences.

Genome-wide association study (GWAS)—An approach that involves rapidly scanning markers across the complete sets of DNA (genomes) of many people to find genetic variations associated with a particular disease.

Genotype—The complete set of an organism's genetic material. The term is sometimes used to refer to the genes or set of genes for a single trait, such as height or eye color.

Machine learning—A subtype of artificial intelligence (AI) based on the concept that a computer can learn and adapt to new data inputs without human intervention. Applied to polygenic risk scoring, machine learning is said to improve the accuracy of PRS scores as the computer is given new population data without the need for a human operator to adjust the computer's algorithm.

Mendelian disease—A disease caused by a single mutated gene; also called a single-gene disease. These diseases are named for Gregor Mendel (1822–1884), an Austrian monk who discovered the basic principles of inheritance of single-gene traits through experimentation with plants in his garden.

Monogenic disease—Another term for a single-gene disorder.

Multifactorial disorders—A general term for polygenic disorders complicated by the effects of environmental factors. Multifactorial disorders do not have clear patterns of inheritance. They are sometimes called complex diseases or disorders.

Nucleotide—A building block of a nucleic acid (DNA or RNA), consisting of a sugar molecule, a phosphate group, and one of the nitrogen-containing bases (adenine, cytosine, guanine, and thymine in DNA; adenine, cytosine, guanine, and uracil in RNA).

Phenotype—The set of observable characteristics or traits of an organism. It includes physical form and structure, development, metabolic processes, movement, and behavior.

Polygenic—Referring to an inherited disorder or trait whose phenotype is influenced by more than one gene.

Single nucleotide polymorphism (SNP)—A germline substitution of a single nucleotide (any of a group of molecules that form the building blocks of DNA or RNA) at a specific position in a person's genome.

Trait—In genetics, a specific characteristic of an individual organism, such as height, weight, or blood type. Traits are determined both by genes and the interaction of the environment with genes.

strategies, and develop new treatments for these diseases, more work needs to be done to improve the accuracy of polygenic risk scoring. The growing number and size of biobanks, along with increases in population sampling size and standardized reporting guidelines, should add to the clinical applicability of PRS. In addition, some private health care companies, including Myriad and Ambry Genetics, are already offering polygenic risk scoring for hereditary cancers, and direct-to-consumer (DTC) genetic testing companies are beginning to make polygenic risk scores available to their customers; 23andMe calls them “health predisposition reports.”

Clinical trials of PRS

In 2021, there were 17 clinical trials of PRS registered with the National Institutes of Health (NIH). The most extensive was a trial of PRS for six complex diseases with established preventive strategies: CAD, atrial fibrillation, type 2 diabetes, colorectal cancer, prostate cancer, and breast cancer. The trial was conducted at a Department of Veterans Affairs (VA) hospital in order to test the clinical effectiveness of PRS as measured by changes in primary health care providers' management of their patients. Six other clinical trials were focused on PRS for breast cancer screening; two on the use of PRS

QUESTIONS TO ASK YOUR DOCTOR

- How do you think PRS could be helpful in your clinical practice?
- Have any of your patients used DTC genetic testing to estimate their risk of a complex disease?
- If PRS becomes widespread in clinical practice, how would you counsel a patient who is at high risk of an incurable disease like Huntington's or ALS (Lou Gehrig's disease)?
- Would you consider participating in a PRS study?

in screening for coronary artery disease; and one on PRS in children at risk of type 2 diabetes.

Pompe disease

Definition

Pompe disease, also called acid maltase deficiency, is a non-sex-linked recessive genetic disorder that is the most serious of the glycogen storage diseases affecting muscle tissue. It is one of several known congenital (present at birth) muscular diseases (myopathies), which are distinct from a muscular dystrophy, which is a family of muscle disorders arising from faulty nutrition. The Dutch pathologist J. C. Pompe first described this genetic disorder in 1932.

Description

Pompe disease is also known as glycogen storage disease type II (GSD II) because it is characterized by a buildup of glycogen in the muscle cells. Glycogen is the chemical substance muscles use to store sugars and starches for later use. Some of the sugars and starches from the diet that are not immediately put to use are converted into glycogen and then stored in the muscle cells. These stores of glycogen are then broken down into sugars as the muscles require them. Acid maltase is the chemical substance that regulates the amount of glycogen stored in muscle cells. When too much glycogen begins to accumulate in a muscle cell, acid maltase is released to break down this excess glycogen into products that will be either reabsorbed for later use in other cells or passed out of the body via the digestive system. Individuals affected with Pompe disease have either a complete inability or a severely limited ability to produce acid maltase. Since these individuals cannot produce the amounts of acid maltase required to process excess glycogen in the muscle cells, the muscle cells become overrun with glycogen. This excess glycogen in the muscle cells causes a progressive degeneration of the muscle tissues.

Acid maltase is an enzyme. An enzyme is a chemical that facilitates (catalyzes) the chemical reaction of another chemical or of other chemicals; it is neither a reactant nor a product in the chemical reaction that it catalyzes. As a result, enzymes are not used up in chemical reactions, but rather recycled. One molecule of an enzyme may be used to catalyze the same chemical reaction over and over again several hundreds of thousands of times. All the enzymes necessary for catalyzing the various reactions of human life are produced within the body by genes. Genetic enzyme deficiency disorders, such as Pompe disease, result from only one cause: the affected individual cannot produce enough of the necessary enzyme because the gene designed to make the enzyme is faulty. Enzymes are not used up in chemical reactions, but they do eventually wear out or accidentally get

expelled. Also, as an individual grows, he or she may require greater quantities of an enzyme. Therefore, most enzyme deficiency disorders will have a time component to them. Individuals with no ability to produce a particular enzyme may show effects of this deficiency at birth or shortly thereafter. Individuals with only a partial ability to produce a particular enzyme may not show the effects of this deficiency until their need for the enzyme, because of growth or maturation, has outpaced their ability to produce it.

The level of ability of individuals with Pompe disease to produce acid maltase, or their ability to sustain existing levels of acid maltase, are the sole determinants of the severity of the observed symptoms in individuals and the age of onset of these symptoms.

Pompe disease is categorized into three separate types based on the age of onset of symptoms in the affected individual. Type a, or infantile, Pompe disease usually begins to produce observable symptoms in affected individuals between the ages of two and five months. Type b, or childhood, Pompe disease usually begins to produce observable symptoms in affected individuals in early childhood. This type generally progresses much more slowly than infantile Pompe disease. Type c, or adult, Pompe disease generally begins to produce observable symptoms in affected individuals in the third or fourth decades of life. This type progresses even more slowly than childhood Pompe disease.

Genetic profile

The locus of the gene responsible for Pompe disease has been localized to 17q23. The severity of the associated symptoms and the age of onset in affected individuals have been closely tied to the particular mutation at this locus. Three specific mutations and one additional mutation type have been demonstrated to occur along the gene responsible for Pompe disease. Each of these is associated with varying symptoms.

A gene is a particular segment of a particular chromosome. However, within the segment containing a particular gene there are two types of areas: introns and exons. Introns are sections of the segment that do not actively participate in the functioning of the gene. Exons are those sections that do actively participate in gene function. A typical gene consists of several areas that are exons divided by several areas of introns.

One mutation on the gene responsible for the production of acid maltase is a deletion of exon 18. A second mutation on the gene responsible for the production of acid maltase is the deletion of a single base pair of exon 2. Both these mutations are associated with a complete inability of the affected individual to produce acid

maltase. Individuals with these mutations will invariably be affected with infantile (type a) Pompe disease.

The third mutation on the gene responsible for the production of acid maltase is a complicated mutation within intron 1 that causes the cutting-out of exon 2. This mutation is generally not complete in every copy of the gene within a given individual, so it is associated with a partial ability of the affected individual to produce acid maltase. Individuals with this mutation will be affected with either childhood (type b) or, more commonly, adult (type c) Pompe disease. In fact, greater than 70% of all individuals affected with adult Pompe disease possess this particular mutation.

The final mutation class known to occur on the gene responsible for the production of acid maltase is missense at various locations along the various exons. Missense is the alteration of a single coding sequence (codon) that codes for a single amino acid that will be used to build the protein that is the precursor to the acid maltase molecule. These missense mutations generally prevent the production of acid maltase and lead to infantile (type a) Pompe disease.

The exact mutations responsible for the other 30% of the adult (type c) and the remainder of the childhood (type b) Pompe disease cases have not yet been determined.

Demographics

Pompe disease is observed in approximately 1 in every 40,000 live births. It is observed in equal numbers of males and females and across all ethnic subpopulations.

Since Pompe disease is a recessive disorder, both parents must be carriers of the disorder for it to be passed to their children. In the case of carrier parents with one child affected by Pompe disease, there is a 25% likelihood that their next child will also be affected with the disorder. However, because type c (adult) Pompe disease generally does not show symptoms in the affected individual until that individual is past age 30, it is possible for an affected individual to parent children. In this case, the probability of a second child being affected with Pompe disease is 50%. Should two affected individuals bear offspring, the probability of their child being affected with Pompe disease is 100%.

In families with more than one affected child, the symptoms of the siblings will closely correspond. That is, if one child develops infantile Pompe disease, a second child, if affected with the disorder, will also develop the infantile form.

Signs and symptoms

The symptoms of Pompe disease vary depending on the severity of the deficiency of acid maltase in the affected individual. The most acid-maltase-deficient individuals will develop infantile Pompe disease and will exhibit the most severe symptoms. Likewise, the least acid-maltase-deficient individuals will develop adult Pompe disease and have less severe symptoms.

Infantile (type a) Pompe disease is characterized by the so-called “floppy baby” syndrome. This condition is caused by extreme weakness and lack of tone of the skeletal muscles. This observed weakness in the skeletal muscles is accompanied by the much more serious problems of overall weakness of the heart muscle (cardiomyopathy) and the muscles of the respiratory system, primarily the diaphragm. Enlargement of the heart (cardiomegaly), tongue, and liver are also observed. Glycogen accumulation is observed in most tissues of the body.

Childhood (type b) Pompe disease is characterized by weakness of the muscles of the trunk and large muscle mass with little muscle tone. This is due to a buildup of glycogen in the muscle cells. The heart and liver of those affected with childhood maltase deficiency are generally normal. However, there is a progressive weakening of the skeletal and respiratory muscles. The observed muscle weakness in childhood Pompe disease-affected individuals gradually progresses from the muscles of the trunk to the muscles of the arms and the legs. Glycogen accumulation is observed primarily in the muscle tissues.

Adult (type c) Pompe disease is characterized by fatigue in younger affected individuals and by weakness of the muscles of the trunk in older affected individuals. The observed muscle weakness in adult Pompe disease-affected individuals gradually progresses from the muscles of the trunk to the muscles of the arms and the legs. High blood pressure in the artery that delivers blood to the lungs (pulmonary hypertension) is also generally observed in affected adults. Glycogen accumulation is observed primarily in the muscle tissues.

Diagnosis

Infantile Pompe disease is generally diagnosed between the ages of two and five months when symptoms begin to appear. The first indicator of infantile Pompe disease is general weakness and lack of tone (hypotonia) of the skeletal muscles, particularly those of the trunk.

A blood test called a serum CK test is the most commonly used test to determine whether muscular degeneration is causing an observed muscular weakness. It is used to rule out other possible causes of muscle weakness, such as nerve problems. To determine the CK serum

KEY TERMS

Acid maltase—The enzyme that regulates the amount of glycogen stored in muscle cells. When too much glycogen is present, acid maltase is released to break it down into waste products.

Acidosis—A condition of decreased alkalinity resulting from abnormally high acid levels (low pH) in the blood and tissues. Usually indicated by sickly sweet breath, headaches, nausea, vomiting, and visual impairments.

Catalyze—Facilitate. A catalyst lowers the amount of energy required for a specific chemical reaction to occur. Catalysts are not used up in the chemical reactions they facilitate.

Enzyme—A protein that catalyzes a biochemical reaction or change without changing its own structure or function.

Exon—The expressed portion of a gene. The exons of genes are those portions that actually chemically code for the protein or polypeptide that the gene is responsible for producing.

Fibroblast—Cells that form connective tissue fibers like skin.

Glycogen—The chemical substance used by muscles to store sugars and starches for later use. It is composed of repeating units of glucose.

Hypoglycemia—An abnormally low glucose (blood sugar) concentration in the blood.

Intron—That portion of the DNA sequence of a gene that is not directly involved in the formation of the chemical that the gene codes for.

Myopathy—Any abnormal condition or disease of the muscle.

Serum CK test—A blood test that determines the amount of the enzyme creatine kinase (CK) in the blood serum. An elevated level of CK in the blood indicates that muscular degeneration has occurred and/or is occurring.

level, blood is drawn and separated into the part containing the cells and the liquid remaining (the serum). The serum is then tested for the amount of creatine kinase (CK) present. Creatine kinase is an enzyme found almost exclusively in the muscle cells and not typically in high amounts in the bloodstream. Higher than normal amounts of CK in the blood serum indicate that muscular degeneration is occurring—that the muscle cells are breaking open and spilling their contents, including the enzyme

creatine kinase into the bloodstream. Individuals affected with Pompe disease have extremely high serum CK levels. Those affected with infantile Pompe disease have much higher serum CK levels than those affected with the childhood or adult forms. The actual serum CK level, once observed to be higher than normal, can also be used to differentiate between various types of muscular degeneration.

Serum CK levels cannot be used to distinguish Pompe disease from other glycogen storage diseases. Pompe disease (type II glycogen storage disease) is differentially diagnosed from type I glycogen storage disease by blood tests for abnormally low levels of glucose (hypoglycemia) and a low pH, or high acidity (acidosis). Hypoglycemia and acidosis are both characteristic of type I glycogen storage disease, but neither is characteristic of Pompe disease.

It is sometimes possible to determine the abnormally low levels of the acid maltase enzyme in the white blood cells (leukocytes) removed during the blood serum tests. If these levels can be determined and they are abnormally low, a definitive diagnosis of Pompe disease can be made. When the results of this leukocyte test are not clear, Pompe disease types a and b may be positively diagnosed by testing muscle cells removed from the affected individual (muscle biopsy) for the actual absence or lack of sufficient acid maltase. This test is 100% accurate for type a and type b Pompe disease, but it may give improper results for type c Pompe disease. In these hard-to-identify cases of type c Pompe disease, an identical test to that performed on the leukocytes may be performed on cultured fibroblasts grown from a sample from the affected individual. This test is 100% accurate for type c Pompe disease.

Treatment and management

The only potential treatment for this deficiency is enzyme replacement therapy. This approach was initially undertaken in the 1970s for Pompe disease with no success. A new enzyme replacement therapy, which began in 1999, is, however, still being tested in human clinical trials. Animal studies have shown a positive response to enzyme replacement therapy and recombinant gene therapy, particularly for increasing cardiac and respiratory function.

Prognosis

Pompe disease of all three types is 100% fatal. Individuals affected with infantile Pompe disease generally die from heart or respiratory failure prior to age one. Individuals affected with childhood Pompe disease generally die from respiratory failure between the ages of three

QUESTIONS TO ASK YOUR DOCTOR

- What is the prognosis for my child?
- How can we improve my child's quality of life?
- How often should my child be assessed for cardiac and respiratory decline?
- What are the chances any future children will have Pompe disease, and what are the ways we can screen for it?
- Are there support groups for me and my child?
- How rapid or slow of a progression do you anticipate with this disease?
- What signs/symptoms that indicate a decline in function should we watch for?
- Is ERT or any other therapy a choice for us, and, if so, what are the chances of the therapy taking effect?
- Are we a candidate to be involved in current clinical trials?

and 24. Individuals affected with adult Pompe disease generally die from respiratory failure within ten to 20 years of the onset of symptoms.

Human clinical trials involving enzyme replacement therapy, in which a synthetic form of acid maltase is administered to affected individuals, were begun in 1999 at Duke University Medical Center in North Carolina and Erasmus University Rotterdam in the Netherlands. Genzyme Corporation and Pharming Group N. V. announced the first results of these trials in a joint press release on October 5, 2000. These two companies currently own the worldwide patent rights to the synthetic enzyme being studied. In 2015, these clinical trials were in phase II of the three-stage testing process for use in humans.

Pontocerebellar hypoplasia (PCH)

Definition

CLP1 is a gene that produces the CLP1 protein that is essential for translating DNA into protein via RNA. In 2014, researchers discovered that mutations (changes) in the *CLP1* gene cause pontocerebellar hypoplasia type 10 (PCH10), an extremely rare disorder that is characterized by the degeneration of both the central nervous system (brain and spinal cord) and the peripheral nervous system located throughout the body.

Description

Pontocerebellar hypoplasia (PCH) encompasses at least ten different disorders that are characterized by the underdevelopment of the brain, especially the parts of the brain called the cerebellum and the pons. The cerebellum, located at the back of the brain, is responsible for coordinating movement. The pons, which is located in the brain stem at the base of the brain, is responsible for transmitting signals between the cerebellum and the rest of the brain. Although the signs and symptoms of different types of PCH vary, they are all characterized by delayed psychomotor development (voluntary movement directed by the brain), movement problems, and intellectual or cognitive defects. Because PCH impairs the growth of other parts of the brain in addition to the pons and cerebellum, it causes a small head and brain (microcephaly). Some types of PCH are caused by different mutations in the same gene, resulting in overlapping

symptoms. *PCH* type 1 (*PCH1*) and type 2 (*PCH2*) are the major forms of this disorder.

PCH10 is a severe, inherited neurodevelopmental and neurodegenerative disorder. It is a novel form of *PCH* that is extremely rare and affects both sensory and motor nerve cells (neurons). *PCH10* is characterized by much delayed motor development, failure of the head and brain to grow (progressive microcephaly), and brain abnormalities. In addition to a small cerebellum and pons, these abnormalities include delayed myelination (the formation of the protective myelin covering of nerve cell axons that form the white matter of the brain) and brain degeneration (atrophy). *PCH10* also causes overall delays in growth and development, severe intellectual disability, spasticity, and seizures that are resistant to treatment. Children with *PCH10* have characteristic facial features.

Mutations in the *CLP1* gene are responsible for *PCH10*. “*CLP1*” stands for “cleavage and polyadenylation factor I subunit 1.” The *CLP1* gene produces a *CLP1* protein called an RNA kinase. Kinases are enzymes that add phosphate groups to other proteins in a process called phosphorylation. *CLP1* was first identified in human cells in 2007, making it the first known RNA kinase in mammals.

CLP1 has several different functions. It is a component of the protein complexes that splice (cleave and rejoin) molecules called transfer RNAs (tRNAs) and messenger RNAs (mRNAs). tRNAs add amino acids to growing polypeptide chains during protein synthesis, according to the instructions contained in mRNAs that are copied (transcribed) from the DNA of genes. After tRNAs are transcribed from their corresponding genes, they must undergo a series of complicated alterations, including splicing, before they are functional. Some of these alterations require the *CLP1* protein. *CLP1* is also involved in the processing or maturation of mRNAs and small interfering RNAs (siRNAs). siRNAs are important for regulating the translation of mRNAs into proteins. Thus, *CLP1* has very important functions in cells throughout the body. Although the production and processing of tRNAs are essential to all cells of the body, mutations in the genes involved in these processes appear to particularly affect the functioning of neurons in the central and peripheral nervous systems. Disorders such as *PCH10*, which affect the production of tRNAs, represent a newly recognized class of neurological disorders.

In 2013, researchers showed that mice lacking the *CLP1* gene progressively lost their spinal motor neurons. The axons (projections that transmit nerve impulses) of their peripheral nerves also degenerated, as did the junctions where nerve cells stimulate muscle. These losses resulted in impaired movement and muscle weakness

KEY TERMS

Autosomal recessive—A gene located on a chromosome other than the X or Y sex chromosomes and carrying a trait or mutation that is not expressed unless the second copy of the same gene inherited from the other parent is also recessive or mutated.

Cerebellum—The part of the brain between the brain stem and back of the cerebrum, consisting of two lateral lobes and a median lobe and involved especially in muscle coordination and maintenance of equilibrium.

Consanguineous—People who are closely related, such as first cousins.

Microcephaly—An abnormally small head, often accompanied by a small, underdeveloped brain.

Pons—A mass of nerve fibers in the brain stem that relay nerve impulses between the cerebellum and the rest of the brain.

Pontocerebellar hypoplasia (PCH)—Underdevelopment of the pons and cerebellum of the brain; *PCH10* is caused by a mutation in the *CLP1* gene.

Transfer RNA (tRNA)—Relatively small RNA (ribonucleic acid) that is responsible for adding a specific amino acid to the growing polypeptide chain of a protein; specific tRNAs must be produced for each of the 20 or so amino acids in proteins.

and eventually led to paralysis and death from respiratory failure. Human *CLP1* gene mutations, and the resulting neurologic disorder *PCH10*, which also affects both the central and peripheral nervous systems, were first reported in 2014.

Genetic profile

The *CLP1* gene is located at position 12 on the long arm (q) of chromosome 11 (11q12). Mutated *CLP1* genes are inherited in an autosomal recessive pattern. This means that the development of *PCH10* requires inheriting two mutated *CLP1* genes, one from each parent, so that the cells of the body cannot make any functional *CLP1* protein. The inheritance of a mutated gene from each parent is more likely if the parents are closely related to each other (consanguineous). The parents, whose cells all have one normal *CLP1* gene and one mutated *CLP1* gene, do not usually have signs and symptoms of the disorder; however, each of their children has a 25% risk of inheriting two mutated *CLP1* genes and developing *PCH10*. Each of their children has an additional 50% risk of

inheriting one mutated *CLP1* gene that can be passed on to offspring.

In 2014, two groups of researchers independently identified the same missense mutation in both *CLP1* genes of multiple children with PCH10 from nine consanguineous Turkish families. Missense mutations change a single building block (nucleotide) in the DNA sequence of a gene so that the three-nucleotide sequence no longer codes for an amino acid in a protein; as a result, no protein is produced from that gene. Genetic analysis also revealed that all of the mutated *CLP1* genes in the affected children had originated from the same single original mutation in a common ancestor. This phenomenon is called a “founder effect.” The researchers further demonstrated that this absence of the CLP1 protein prevented the proper splicing of tRNAs.

Demographics

PCH10, as well as types of PCH other than PCH1 and PCH2, appear to be extremely rare. They have been reported in very few individuals.

Signs and symptoms

Brain abnormalities associated with PCH10 are present at birth, and signs and symptoms of the condition develop within the first months of life. Some signs and symptoms may also occur with other types of PCH, and include:

- Microcephaly that is usually not apparent at birth but becomes obvious during infancy and early childhood as brain growth slows
- Characteristic facial features that include highly arched eyebrows, prominent eyes, strabismus (lack of binocular vision due to imbalanced eyeball muscles), long palpebral fissures (the space between the margins of the eyelids), long eyelashes, and a broad nose
- Developmental delays, including failure to develop gross and fine motor skills and speech that is absent or delayed
- Lack of head control
- Inability to sit unsupported or walk
- Severe intellectual disabilities
- Seizures that do not respond to treatment
- Poor overall growth
- Progressively spastic limbs with excessive muscle tone and increased tendon reflexes
- Severe degeneration of the axons of both motor and sensory nerves

QUESTIONS TO ASK YOUR DOCTOR

- What are the signs and symptoms of pontocerebellar hypoplasia?
- Can pontocerebellar hypoplasia be detected prenatally?
- Should family members be tested for a mutated CLP1 gene?
- What is the risk that a couple will have a second child with pontocerebellar hypoplasia type 10?
- What is the prognosis for a child with pontocerebellar hypoplasia?

Diagnosis

The brain and other abnormalities associated with PCH can sometimes be detected by prenatal ultrasound. Brain imaging, such as magnetic resonance imaging (MRI), can reveal the underdevelopment and structural defects of the cerebellum and pons, as well as thinning of the brain stem and the corpus callosum (the fibers connecting the two hemispheres of the brain), enlarged ventricles (the cavities within the brain containing the cerebrospinal fluid), and possibly abnormalities of the white matter (myelinated nerve axons) of the brain. MRIs of the brain and spinal cord, computed axial tomography (CAT or CT) scans of the brain, ultrasound imaging, and metabolic analysis may be used to rule out other causes of the brain abnormalities. Electromyography and nerve conduction tests will show significant degeneration of sensory and motor neurons in the spinal cord and the peripheral nervous system. Electroencephalography (EEG)—tests of electrical activity in the brain—may also be performed. Ophthalmologic evaluation for vision problems is usually required. In 2015, identification of *CLP1* gene mutations required sequencing the entire region of the gene that codes for the CLP1 protein.

Treatment and management

Treatment of PCH10 is symptomatic and supportive. It is directed at ameliorating apparent symptoms.

Prognosis

Many children with PCH do not survive infancy or live only into childhood. Occasionally, individuals affected by some types of PCH have been known to survive into adulthood.

Porphyrrias

Definition

The porphyrias comprise a group of eight metabolic disorders in which the body produces too much porphyrin and insufficient heme, the iron-containing molecule found, for example, in hemoglobin, the oxygen-carrier protein. Porphyrins are precursor molecules for heme and certain enzymes. Excess porphyrins are excreted as waste in the urine and stool. Overproduction and overexcretion of porphyrins cause low, unhealthy levels of heme and certain important enzymes, creating various physical symptoms.

Description

Biosynthesis of heme is a multistep process that begins with simple molecules and ends with a large, complex heme molecule. Each step of the chemical pathway is directed by its own task-specific protein, called an

Early symptoms of porphyrias including blistering on the hands, face, and arms following minor injuries or exposure to sunlight. (Zara/BSIP SA/Alamy)

enzyme. As a heme precursor molecule moves through each step, an enzyme modifies the precursor for the next step. If a precursor molecule is not modified, it cannot proceed further in the pathway, causing a build-up of that specific precursor.

The precursors prevented from proceeding further along the pathway accumulate at the stage of the enzyme defect, causing an array of physical symptoms in an affected person. Specific symptoms depend on the point at which heme biosynthesis is blocked and which precursors accumulate. In general, the porphyrias primarily affect the skin and the nervous system. Symptoms can be debilitating or life-threatening in some cases. Porphyria is most commonly an inherited condition. It can also, however, be acquired after exposure to poisonous substances.

Heme

Heme is produced in several tissues in the body, but its primary biosynthesis sites are the liver and bone marrow. Heme synthesis for immature red blood cells, namely the erythroblasts and the reticulocytes, occurs in the bone marrow.

Although production is concentrated in the liver and bone marrow, heme is utilized in various capacities in virtually every tissue in the body. In most cells, heme is a key building block in the construction of factors that oversee metabolism and transport of oxygen and energy. In the liver, heme is a component of several vital enzymes, particularly cytochrome P450. Cytochrome P450 is involved in the metabolism of chemicals, vitamins, fatty acids, and hormones; it is very important in transforming toxic substances into easily excretable materials. In immature red blood cells, heme is the crucial

component of hemoglobin, the biomolecule that carries oxygen in red blood cells.

Heme biosynthesis

The heme molecule consists of a cyclic porphyrin molecule containing a central iron atom. The heme biosynthesis pathway is a series of steps building the complete heme molecule, and the last step involves incorporation of the iron atom.

The production of heme may be compared to a factory assembly line. At the start of the line, raw materials are fed into the process. At specific points along the line, an addition or adjustment is made to further development. Once additions and adjustments are complete, the final product rolls off the end of the line.

Heme biosynthesis is an eight-step process, requiring eight different and properly functioning enzymes:

- delta-aminolevulinic acid synthase
- delta-aminolevulinic acid dehydratase
- uroporphobilinogen deaminase
- uroporphyrinogen III cosynthase
- uroporphyrinogen decarboxylase
- coproporphyrinogen oxidase
- protoporphyrinogen oxidase
- ferrochelatase

The control of heme biosynthesis is complex. Various chemical signals can trigger increased or decreased production. These signals can affect the enzymes themselves or the production of these enzymes, starting at the genetic level. For example, one point at which heme biosynthesis may be controlled is at the first step. When heme levels are low, greater quantities of delta-aminolevulinic acid (ALA) synthase are produced. As a result, larger quantities of heme precursors are fed into the biosynthesis pathway to step up heme production.

Types of porphyrias

Under normal circumstances, when heme concentrations are at an appropriate level, precursor production decreases. However, a defective enzyme can prevent heme biosynthesis from reaching completion. Because heme levels remain low, the synthesis pathway continues to churn out precursor molecules in an attempt to correct the heme deficit.

The net effect of this continued production is an abnormal accumulation of precursor molecules and development of some type of porphyria. Each type of porphyria corresponds to a specific enzyme defect and an accumulation of the associated precursor. Although there are eight steps in heme biosynthesis, there are only

seven types of porphyrias; a change in ALA synthase activity does not have a corresponding porphyria.

Enzymes involved in heme biosynthesis display subtle, tissue-specific variations; therefore, heme biosynthesis may be impaired in the liver, but normal in the immature red blood cells, or vice versa. Incidence of porphyria varies widely between types and occasionally by geographic location. Although certain porphyrias are more common than others, their greater frequency is only relative to other types. All porphyrias are considered to be rare disorders.

In the past, the porphyrias were divided into two general categories based on the location of the porphyrin production. Porphyrias affecting heme biosynthesis in the liver were referred to as hepatic porphyrias. Porphyrias affecting heme biosynthesis in immature red blood cells were referred to as erythropoietic porphyrias (erythropoiesis is the process through which red blood cells are produced). Porphyrias are usually grouped into acute and nonacute types. Acute porphyrias produce severe attacks of pain and neurological effects. Nonacute porphyrias present as chronic diseases.

The acute porphyrias, and the heme biosynthesis steps at which enzyme problems occur, are:

- ALA dehydratase deficiency porphyria (step 2): the enzyme aminolevulinic acid dehydratase is deficient.
- Acute intermittent porphyria, also known as Swedish porphyria, pyroloporphyria, and intermittent acute porphyria (step 3): the enzyme uroporphobilinogen deaminase is deficient.
- Hereditary coproporphyria (step 6): the enzyme coproporphyrinogen oxidase is deficient.
- Variegate porphyria (VP), also known as porphyria variegata, protocoproporphyria, South African genetic porphyria, and Royal malady (supposedly King George III of England and Mary, Queen of Scots, had VP) (step 7): the enzyme protoporphyrinogen oxidase is deficient.

The nonacute porphyrias, and the steps of heme biosynthesis at which they occur, are:

- Congenital erythropoietic porphyria (CEP), also called Gunther's disease, erythropoietic porphyria, congenital porphyria, congenital hematoporphyria, or erythropoietic uroporphyria, is a rare disease (step 4): the enzyme uroporphyrinogen III synthase is deficient.
- Porphyria cutanea tarda (PCT), also called symptomatic porphyria, porphyria cutanea symptomatica, or idiosyncratic porphyria (step 5): the enzyme uroporphyrinogen decarboxylase is deficient. PCT may be acquired, typically as a result of disease (especially hepatitis C), or inherited. Most people remain latent—that is, symptoms never develop.

- Hepatoerythropoietic porphyria (HEP) (also step 5). HEP affects heme biosynthesis in both the liver and the bone marrow. HEP also results from a defect in uroporphyrinogen decarboxylase activity. Disease symptoms, however, strongly resemble congenital erythropoietic porphyria.
- Erythropoietic protoporphyria (EPP), also known as protoporphyria and erythrohepatic protoporphyria (step 8): ferrochelatase is the deficient enzyme.

Genetic profile

The underlying cause of all porphyrias is a deficiency of one of the enzymes involved in the heme biosynthesis pathway. Porphyrias are inherited conditions, and in virtually all types, an inherited factor causes the enzyme deficiency. An environmental factor—such as diet, drugs, or sun exposure—may trigger symptoms, but in many cases, symptoms never develop.

Each of the seven porphyrias has a specific inheritance pattern and a gene mutation responsible for its occurrence:

- ALA dehydratase porphyria: autosomal recessive inheritance, due to a mutation of the *ALAD* gene in chromosome 9q34. This porphyria type is very rare. In autosomal recessively inherited disorders, a person must inherit two defective genes, one from each parent. A parent with only one gene for an autosomal recessive disorder does not display symptoms of the disease.
- Acute intermittent porphyria: autosomal dominant inheritance, due to a mutation of the *PBGD* gene in chromosome 11q23.3. An autosomal dominant pattern, which means that only one copy of the abnormal gene needs to be present for the disorder to occur. Simply inheriting this gene, however, does not necessarily mean that a person will develop the disease. Approximately 5 to 10 per 100,000 persons in the United States carry a gene for AIP, but only 10% of these people ever develop symptoms of the disease.
- Congenital erythropoietic porphyria: autosomal recessive inheritance, due to a mutation of the *UROS* gene in chromosome 10q25.2–q26.3.
- Porphyria cutanea tarda: autosomal dominant or sporadic inheritance, due to a mutation of the *UROD* gene in chromosome 1p34.
- Hereditary coproporphyria: autosomal dominant inheritance, due to a mutation of the *CPOX* gene in chromosome 3q12.
- Variegate porphyria: autosomal dominant inheritance, due to a mutation of the *PPOX* gene in chromosome 1q22.

- Erythropoietic protoporphyria: autosomal dominant inheritance, due to a mutation of the *FECH* gene in chromosome 18q21.3.

Demographics

Porphyrias are rare conditions and are often misdiagnosed because their symptoms are easily confused with other diseases. Congenital erythropoietic porphyria is typically seen in early childhood; erythropoietic protoporphyria in older childhood; acute intermittent porphyria, variegate porphyria, hereditary coproporphyria, and delta-aminolevulinic acid dehydratase deficiency porphyria in teens and young adults; and porphyria cutanea tarda in adults older than 40 years of age. The most common form of porphyria worldwide is porphyria cutanea tarda. In 2012, the prevalence of PCT in the world was estimated at 10 cases in 100,000; the prevalence of acute intermittent porphyria, erythropoietic protoporphyria, and variegate porphyria at 1–10 of 100,000 people; and hereditary coproporphyria at less than 1 in 100,000 of the population. Delta-aminolevulinic acid dehydratase deficiency porphyria and congenital erythropoietic porphyria are both extremely rare.

Signs and symptoms

General characteristics

All of the hepatic porphyrias—except porphyria cutanea tarda—follow a pattern of acute attacks separated by periods in which no symptoms are present. For this reason, this group is often referred to as the acute porphyrias. The erythropoietic porphyrias and porphyria cutanea tarda do not follow this pattern and are considered to be chronic conditions.

The specific symptoms of each porphyria vary based on which enzyme is affected and whether that enzyme occurs in the liver or in the bone marrow. The severity of symptoms can vary widely, even within the same type of porphyria. If the porphyria becomes symptomatic, the common factor between all types is an abnormal accumulation of protoporphyrins or porphyrin.

ALA dehydratase porphyria (ADP)

ADP is characterized by a deficiency of ALA dehydratase. Of the few cases on record, the prominent symptoms were vomiting; pain in the abdomen, arms, and legs; and neuropathy. (Neuropathy refers to nerve damage that can cause pain, numbness, or paralysis.) The nerve damage associated with ADP could cause breathing impairment or lead to weakness or paralysis of the arms and legs.

Acute intermittent porphyria (AIP)

Symptoms of AIP usually do not occur unless a person with the deficiency encounters a trigger substance. Trigger substances can include hormones (for example, oral contraceptives, menstruation, pregnancy), drugs, and dietary factors. Most people with this deficiency never develop symptoms.

Attacks occur after puberty and commonly feature severe abdominal pain, nausea, vomiting, and constipation. Muscle weakness and pain in the back, arms, and legs are also typical symptoms. During an attack, the urine is a deep reddish color. The central nervous system may also be involved. Possible psychological symptoms include hallucinations, confusion, seizures, and mood changes.

Congenital erythropoietic porphyria (CEP)

Symptoms of CEP are often apparent in infancy and include reddish urine and possibly an enlarged spleen. The skin is unusually sensitive to light and blisters easily if exposed to sunlight. (Sunlight induces protoporphyrin changes in the plasma and skin. These altered protoporphyrin molecules can cause skin damage.) Increased hair growth is common. Damage from recurrent blistering and associated skin infections can be severe. In some cases facial features and fingers may be lost to recurrent damage and infection. Deposits of protoporphyrins can sometimes lead to red staining of the teeth and bones.

Porphyrria cutanea tarda (PCT)

PCT may occur as an acquired or an inherited condition. The acquired form usually does not appear until adulthood. The inherited form may appear in childhood, but often demonstrates no symptoms. Early symptoms include blistering on the hands, face, and arms following minor injuries or exposure to sunlight. Lightening or darkening of the skin may occur along with increased hair growth or loss of hair. Liver function is abnormal but the signs are mild.

Hepatoerythropoietic porphyria (HEP)

The symptoms of HEP are similar to those of CEP.

Hereditary coproporphyrria (HCP)

HCP is similar to AIP, but the symptoms are typically milder. The greatest difference between HCP and AIP is that people with HCP may have some skin sensitivity to sunlight. However, extensive damage to the skin is rarely seen.

Variegate porphyria (VP)

Like AIP, symptoms of VP occur only during attacks. Major symptoms of this type of porphyria include neurological problems and sensitivity to light. Areas of the skin that are exposed to sunlight are susceptible to burning, blistering, and scarring.

Erythropoietic protoporphyria (EPP)

Owing to deficient ferrochelatase, the last step in the heme biosynthesis pathway—the insertion of an iron atom into a porphyrin molecule—cannot be completed. The major symptoms of this disorder are related to sensitivity to light—including both artificial and natural light sources. Following exposure to light, a person with EPP experiences burning, itching, swelling, and reddening of the skin. Blistering and scarring may occur but are neither common nor severe. EPP is associated with increased risks for gallstones and liver complications. Symptoms can appear in childhood and tend to be more severe during the summer when exposure to sunlight is more likely.

Diagnosis

Depending on the array of symptoms an individual may exhibit, the possibility of porphyria may not immediately come to a physician's mind. In the absence of a family history of porphyria, nonspecific symptoms, such as abdominal pain and vomiting, may be attributed to other disorders. Neurological symptoms, including confusion and hallucinations, can lead to an initial suspicion of psychiatric disease. Diagnosis is more easily accomplished in cases in which nonspecific symptoms appear in combination with symptoms more specific to porphyria, like neuropathy, sensitivity to sunlight, or certain other manifestations. Certain symptoms, such as urine the color of port wine, are hallmark signs very specific to porphyria. As of 2015, DNA analysis was becoming more widely used for the diagnosis of a porphyria. After a urine analysis identifies a porphyria is present, mutation analysis can be performed. Identifying the genetic cause of the porphyria is extremely beneficial in the treatment and management of the case, proving DNA testing to be essential in the diagnosis of the syndrome.

A common initial test measures protoporphyrins in the urine. However, if skin sensitivity to light is a symptom, a blood plasma test is indicated. If these tests reveal abnormal levels of protoporphyrins, further tests are done to measure heme precursor levels in red blood cells and the stool. The presence and estimated quantity of porphyrin and protoporphyrins in biological samples are easily detected using spectrofluorometric testing. Spectrofluorometric testing uses a spectrofluorometer that directs light of a specific strength at a fluid sample. The porphyrins

KEY TERMS

Autosomal dominant—A pattern of genetic inheritance where only one abnormal gene is needed to display the trait or disease.

Autosomal recessive—A pattern of genetic inheritance where two abnormal genes are needed to display the trait or disease.

Biosynthesis—The manufacture of materials in a biological system.

Bone marrow—A spongy tissue located in the hollow centers of certain bones, such as the skull and hip bones. Bone marrow is the site of blood cell generation.

Enzyme—A protein that catalyzes a biochemical reaction or change without changing its own structure or function.

Erythropoiesis—The process through which new red blood cells are created; it begins in the bone marrow.

Erythropoietic—Referring to the creation of new red blood cells.

Gene—A building block of inheritance, which contains the instructions for the production of a particular protein, and is made up of a molecular sequence found on a section of DNA. Each gene is found on a precise location on a chromosome.

Hematin—A drug administered intravenously to halt an acute porphyria attack. It causes heme biosynthesis to decrease, preventing the further accumulation of heme precursors.

Heme—The iron-containing molecule in hemoglobin that serves as the site for oxygen binding.

Hemoglobin—Protein-iron compound in the blood that carries oxygen to the cells and carries carbon dioxide away from the cells.

Hepatic—Referring to the liver.

Neuropathy—A condition caused by nerve damage. Major symptoms include weakness, numbness, paralysis, or pain in the affected area.

Porphyrin—A large cyclic molecule shaped like a four-leaf clover. Combined with an iron atom, it forms a heme molecule.

Protoporphyrin—A precursor molecule to the porphyrin molecule.

Whether heme precursors occur in the blood, urine, or stool gives some indication of the type of porphyria, but more detailed biochemical testing is required to determine their exact identity. Making this determination yields a strong indicator of which enzyme in the heme biosynthesis pathway is defective; this, in turn, allows a diagnosis of the particular type of porphyria.

Biochemical tests rely on the color, chemical properties, and other unique features of each heme precursor. For example, a screening test for acute intermittent porphyria (AIP) is the Watson-Schwartz test. In this test, a special dye is added to a urine sample. If one of two heme precursors—porphobilinogen or urobilinogen—is present, the sample turns pink or red. Further testing is necessary to determine whether the precursor present is porphobilinogen or urobilinogen—only porphobilinogen is indicative of AIP.

Other biochemical tests rely on the fact that heme precursors become less soluble in water (able to be dissolved in water) as they progress further through the heme biosynthesis pathway. For example, to determine whether the Watson-Schwartz urine test is positive for porphobilinogen or urobilinogen, chloroform is added to the test tube. Chloroform is a water-insoluble substance. Even after vigorous mixing, the water and chloroform separate into two distinct layers. Urobilinogen is slightly insoluble in water, while porphobilinogen tends to be water-soluble. The porphobilinogen mixes more readily in water than chloroform, so if the water layer is pink (from the dye added to the urine sample), that indicates the presence of porphobilinogen, and a diagnosis of AIP is probable.

As a final test, measuring specific enzymes and their activities may be done for some types of porphyrias; however, such tests are not done as a screening method. Certain enzymes, such as porphobilinogen deaminase (the abnormal enzyme in AIP), can be easily extracted from red blood cells; other enzymes, however, are less readily collected or tested. Basically, an enzyme test involves adding a certain amount of the enzyme to a test tube that contains the precursor it is supposed to modify. Both the production of modified precursor and the rate at which it appears can be measured using laboratory equipment. If a modified precursor is produced, the test indicates that the enzyme is doing its job. The rate at which the modified precursor is produced can be compared to a standard to measure the efficiency of the enzyme.

Treatment and management

Treatment for porphyria revolves around avoiding acute attacks, limiting potential effects, and treating

and protoporphyrins in the sample absorb the light energy and fluoresce, or glow. The spectrofluorometer detects and measures fluorescence, which indicates the amount of porphyrins and protoporphyrins in the sample.

symptoms. Treatment options vary depending on the specific type of porphyria diagnosed. Gene therapy has been successful for both CEP and EPP. In the future, scientists expect development of gene therapy for the remaining porphyrias. Given the rarity of ALA dehydratase porphyria, definitive treatment guidelines for this rare type have not been developed.

For the most part, the porphyrias are attributed to inherited genes; such inheritance cannot be prevented. However, symptoms can be limited or prevented by avoiding factors that trigger symptom development.

People with a family history of an acute porphyria should be screened for the disease. Even if symptoms are absent, it is useful to know about the presence of the gene to assess the risks of developing the associated porphyria. This knowledge also reveals whether a person's offspring may be at risk. Prenatal testing for certain porphyrias is possible. Prenatal diagnosis of congenital erythropoietic porphyria has been successfully accomplished. Any prenatal tests, however, would not indicate whether a child would develop porphyria symptoms, only that they might have the potential to do so.

Acute intermittent porphyria, hereditary coproporphyria, and variegate porphyria

Treatment for acute intermittent porphyria, hereditary coproporphyria, and variegate porphyria follows the same basic regime. A person who has been diagnosed with one of these porphyrias can prevent most attacks by avoiding precipitating factors, such as certain drugs that have been identified as triggers for acute porphyria attacks. Individuals must maintain adequate nutrition, particularly in respect to carbohydrates. In some cases, an attack can be stopped by increasing carbohydrate consumption or by receiving carbohydrates intravenously.

When attacks occur, prompt medical attention is necessary. Pain is usually severe, and narcotic analgesics are the best option for relief. Phenothiazines can be used to counter nausea, vomiting, and anxiety, and chloral hydrate or diazepam is useful for sedation or to induce sleep. Hematin, a drug administered intravenously, may be used to halt an attack. Hematin seems to work by signaling the pathway of heme biosynthesis to slow production of precursors. Women, who tend to develop symptoms more frequently than men owing to hormonal fluctuations, may find ovulation-inhibiting hormone therapy to be helpful.

QUESTIONS TO ASK YOUR DOCTOR

- Porphyria runs in our family. How can I find out if I have the disorder or carry a defective gene for the condition?
- What are the chances that one or more of my children will inherit a form of porphyria?
- Is pregnancy a possible risk for women who have porphyria?
- If one of my children inherits porphyria, how serious is the disease likely to be?

Gene therapy is a possible future treatment for these porphyrias. An experimental animal model of AIP has been developed and research is in progress.

Liver transplant may also be necessary and successful for treating patients with life-threatening manifestation of acute intermittent porphyria.

Congenital erythropoietic porphyria

The key points of congenital erythropoietic porphyria treatment are avoiding exposure to sunlight and prevention of skin trauma or skin infection. Liberal use of sunscreens and consumption of beta-carotene supplements can provide some protection from sun-induced damage. Medical treatments such as removing the spleen or administering transfusions of red blood cells can create short-term benefits, but these treatments do not offer a cure. Remission can sometimes be achieved after treatment with oral doses of activated charcoal. Severely affected patients may be offered bone marrow transplantation, which appears to confer long-term benefits.

Porphyria cutanea tarda

As with other porphyrias, the first line of defense is avoidance of factors, especially alcohol, that could bring about symptoms. Regular blood withdrawal is a proven therapy for pushing symptoms into remission. If an individual is anemic or cannot have blood drawn for other reasons, chloroquine therapy may be used.

Erythropoietic protoporphyria

Avoiding sunlight, using sunscreens, and taking beta-carotene supplements are typical treatment options for erythropoietic protoporphyria. The drug cholestyramine may reduce the skin's sensitivity to sunlight as well as the accumulated heme precursors in the liver.

Liver transplantation has been used in cases of liver failure, but it has not provided a long-term cure of the porphyria.

Alternative treatment

Acute porphyria attacks can be life-threatening events, so attempts at self-treatment can be dangerous. Alternative treatments can be useful adjuncts to conventional therapy. For example, some people may find relief for the pain associated with acute intermittent porphyria, hereditary coproporphyria, or variegate porphyria through acupuncture or hypnosis. Relaxation techniques, such as yoga or meditation, may also prove helpful in pain management.

Prognosis

Even when porphyria is inherited, symptom development depends on a variety of factors. In the majority of cases, a person remains asymptomatic throughout life. About one percent of acute attacks can be fatal. Other symptoms may be associated with temporarily debilitating or permanently disfiguring consequences. Measures to avoid these consequences are not always successful, regardless of how diligently they are pursued. Although pregnancy has been known to trigger porphyria attacks, dangers associated with pregnancy are not as great as was once thought.

Prader-Willi syndrome

Definition

Prader-Willi syndrome (PWS) is a genetic condition caused by the absence of chromosomal material from chromosome 15. The genetic basis of PWS is complex. Characteristics of the syndrome include developmental delay, poor muscle tone, short stature, small hands and feet, incomplete sexual development, and unique facial features. Insatiable appetite is a classic feature of PWS. This uncontrollable appetite can lead to health problems and behavior disturbances.

Description

The first patients with features of PWS were described by Drs. Prader, Willi, and Lambert in 1956. Since that time, the complex genetic basis of PWS has begun to be understood. Initially, scientists found that more than 70% of individuals with PWS have a portion of genetic material deleted (erased) from chromosome 15. Through a process called imprinting, genetic contributions to a child from each parent are activated so that traits from each parent are passed on. In individuals with PWS, the genetic material from chromosome 15 received from one's father is deleted. If the deletion is on the chromosome 15 inherited from one's mother, a different syndrome develops. This was an important discovery. It demonstrated for the first time that the genes inherited from one's mother can be expressed differently from those inherited from one's father.

Over time, scientists discovered that some individuals with PWS, approximately 25%, do not have a deletion of genetic material from chromosome 15. Further studies found that, rather than deleted material from chromosome 15, about 35 percent of patients inherit two copies of chromosome 15 from their mother. Normally, an individual should receive one chromosome 15 from one's

father and one chromosome 15 from one's mother. When a person receives both chromosomes from the same parent, it is called uniparental disomy. When a person receives both chromosomes from one's mother, it is called maternal uniparental disomy. For fewer than 5% of people with PWS, the chromosome 15 locus is present but silenced.

Newborns with PWS generally have poor muscle tone (hypotonia) and do not feed well. This can lead to poor weight gain and failure to thrive. Genitalia can be smaller than normal. Hands and feet are also typically smaller than normal. Some patients with PWS have unique facial characteristics, which are typically subtle and only detectable by physicians.

As children with PWS age, development is typically slower than normal. Developmental milestones, such as crawling, walking, and talking, occur later than usual. Developmental delay continues into adulthood for approximately 50% of individuals with PWS. At about one to two years of age, children with PWS develop an uncontrollable, insatiable appetite. Left to their own devices, individuals with PWS will eat until they have life-threatening obesity. The desire to eat can lead to significant behavior problems.

The symptoms and features of PWS require life-long support and care. If food intake is strictly monitored, and various therapies provided, individuals with PWS can have a normal life expectancy.

Genetic profile

To comprehend the various causes of PWS, the nature of chromosomes and genes must be well understood. Human beings have 46 chromosomes in the cells of their body. Chromosomes contain genes. Genes regulate the function and development of the body. An individual's chromosomes are inherited from their parents. A child should receive 23 chromosomes from their mother and 23 chromosomes from their father.

The 46 chromosomes in the human body are divided into pairs. Each pair is assigned a number or a letter. Chromosomes are divided into pairs based on their physical characteristics. They can only be seen when viewed under a microscope. Chromosomes within the same pair appear identical, because they contain the same genes.

Most chromosomes have a constriction near the center, called the centromere. The centromere separates the chromosome into long and short arms. The short arm of a chromosome is called the "p arm." The long arm of a chromosome is called the "q arm."

Chromosomes in the same pair contain the same genes. However, some genes work differently, depending

Colored X-ray (side view) of the elongated skull (dolichocephalic deformity) in an adult patient. This deformed skull can either characterize newborns who are born after breech presentation, or it may be found in the genetic disorder Prader-Willi syndrome. (Zephyr/Science Source)

on whether they were inherited from the egg or the sperm. Sometimes, genes are silenced when inherited from the mother. Other times, they are silenced when inherited from the father. When genes in a certain region on a chromosome are silenced, they are said to be "imprinted." Imprinting is a normal process and does not typically cause disease. If normal imprinting is disrupted, a genetic disease can develop.

Individuals should have two complete copies of chromosome 15. One chromosome 15 should be inherited from the mother, or be "maternal" in origin. The other chromosome 15 should be inherited from the father, or be "paternal" in origin.

Several genes found on the q arm of chromosome 15 are imprinted. They are normally imprinted, or silenced, if inherited from the mother. The imprinting of this group of maternal genes does not typically cause disease. The genes in this region should not be imprinted if paternal in origin. Normal development depends on these paternal genes being present and active. If these genes are deleted, not inherited, or incorrectly imprinted, PWS develops.

About 60 percent of the cases of PWS are caused when a piece of material is deleted, or erased, from the paternal chromosome 15 (DEL15). This deletion happens in region 11 through 13 on the q arm of chromosome 15. The piece of chromosomal material that is deleted contains genes that must be present for normal development. These paternal genes must be working normally, because the same genes on the chromosome 15 inherited from the mother are imprinted. When these paternal genes are missing, the brain and other parts of the body do not

develop as expected, which is what causes the symptoms associated with PWS.

Researchers have identified two specific mechanisms of genetic mutation that cause Prader-Willi syndrome. Both involve genes located on sections of chromosome 15. One specific genetic cause is a mutation of the *SNORD116* cluster genes. These genes are responsible for the production of a specific type of RNA called small nucleolar RNA (snoRNA), which is involved in the regulations of other RNA. When the snoRNA is abnormal, it leads to the symptoms of PWS. Scientists have not discovered exactly how abnormal snoRNA causes PWS.

Another cause of PWS is a mutation in the *OCA2* gene, which is also located on chromosome 15. When this gene is mutated, it leads to the characteristic light hair and fair skin of some individuals with PWS, because the *OCA2* gene is involved in producing proteins that are important in the formation of pigment in hair, eyes, and skin.

In nearly all cases of PWS caused by a deletion of genetic material, it is sporadic. This means that it happens randomly during fetal development, and there is not an apparent cause. It does not run in families. If a child has PWS due to a sporadic deletion in the paternal chromosome 15, the chance that the parents could have another child with PWS is less than 1%. In fewer than 1% of the cases of PWS, there is a chromosomal rearrangement in a family, which causes the deletion. This chromosomal rearrangement is called a translocation. If a parent has a translocation, the risk of having a child with PWS is higher than 1%.

PWS can also develop if a child receives both chromosome 15s from his or her mother. This is seen in approximately 25% of the cases of PWS. Maternal uniparental disomy for chromosome 15 leads to PWS, because the genes on the chromosome 15 that should have been inherited from the father are missing. These paternal genes must be present, since the same genes on both the chromosome 15s inherited from the mother are imprinted.

PWS caused by maternal uniparental disomy is sporadic, which means that it happens randomly, and there is no apparent cause. If a child has PWS due to maternal uniparental disomy, the chance that the parents could have another child with PWS is less than 1%.

Approximately 3% to 4% of patients with PWS have a change (mutation) in a gene located on the q arm of chromosome 15. This mutation leads to incorrect imprinting and causes genes inherited from the father to be imprinted or silenced. These genes should not normally be imprinted. If a child has PWS due to a mutation that changes imprinting, the chance that the parents could have another child with PWS is approximately 5%.

If an individual has a deletion of the same material from the q arm of the maternal chromosome 15, a different syndrome develops, called Angelman syndrome. Angelman syndrome can also occur if an individual receives both chromosome 15s from their father.

Demographics

PWS affects approximately one in 10,000 to 30,000 live births. It is the most common genetic cause of life-threatening obesity. It affects both males and females. PWS can be seen in all races and ethnic groups.

Signs and symptoms

Infants with PWS have weak muscle tone (hypotonia), which causes problems with sucking and eating. Infants with PWS may have problems gaining weight. Some are diagnosed with failure to thrive, due to slow growth and development. During infancy, babies with PWS may also sleep more than normal and have problems controlling their temperature.

Some of the unique physical features associated with PWS can be seen during infancy. Genitalia that is smaller than normal is common. This may be more evident in males with PWS. Hands and feet may also be smaller than average. The unique facial features seen in some patients with PWS may be difficult to detect in infancy. These facial features are very mild and do not cause physical problems.

As early as six months, but more commonly between one and two years of age, a compulsive desire to eat develops. This uncontrollable appetite is a classic feature of PWS. Individuals with PWS lack the ability to feel full or satiated. This uncontrollable desire to eat is thought to be related to a difference in the brain, which controls hunger. Overeating (hyperphagia), a lack of a desire to exercise, and a slow metabolism place individuals with PWS at high risk for severe obesity. Some individuals with PWS may also have a reduced ability to vomit.

Behavior problems are a common feature of PWS. Some behavior problems develop from the desire to eat. Other reported problems include obsessive-compulsive behaviors, depression, and temper tantrums. Individuals with PWS may also pick their own skin. This unusual behavior may be due to a reduced pain threshold.

Developmental delay, learning disabilities, and intellectual impairment are associated with PWS. Approximately 50% of individuals with PWS have developmental delay. The remaining 50% are described as having mild intellectual impairment, although it can occasionally be more severe.

KEY TERMS

Amniocentesis—A procedure performed at 16 to 18 weeks of pregnancy in which a needle is inserted through a woman's abdomen, into her uterus, to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about various genetic disorders and other medical conditions in the fetus.

Centromere—The centromere is the constricted region of a chromosome. It performs certain functions during cell division.

Deletion—The absence of genetic material that is normally found in a chromosome. Often, the genetic material is missing due to an error in replication of an egg or sperm cell.

Deoxyribonucleic acid (DNA)—The genetic material in cells that holds the inherited instructions for growth, development, and cellular functioning.

FISH (fluorescent in situ hybridization)—A technique used to detect small deletions or rearrangements in chromosomes by attempting to attach a fluorescent (glowing) piece of a chromosome to a sample of cells obtained from a patient.

Gene—A building block of inheritance, which contains the instructions for the production of a particular protein, and is made up of a molecular sequence found on a section of DNA. Each gene is found in a precise location on a chromosome.

Hyperphagia—Overeating.

Hypotonia—Reduced or diminished muscle tone.

Imprinting—A process that silences a gene or group of genes. The genes are silenced depending on whether they are inherited through the egg or the sperm.

Maternal—Relating to the mother.

Maternal uniparental disomy—A chromosome abnormality in which both chromosomes in a pair are inherited from one's mother.

Methylation testing—DNA testing that detects whether a gene is active, or whether it is imprinted.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and can be transmitted to offspring.

Paternal—Relating to one's father.

Translocation—The transfer of one part of a chromosome to another chromosome during cell division. A balanced translocation occurs when pieces from two different chromosomes exchange places without loss or gain of any chromosomal material. An unbalanced translocation involves the unequal loss or gain of genetic information between two chromosomes.

Uniparental disomy—A chromosomal abnormality in which both chromosomes in a pair are inherited from the same parent.

Puberty may occur early or late, but it is usually incomplete. In addition to the effects on sexual development and fertility, individuals do not undergo the normal adolescent growth spurt and may be short as adults. Muscles often remain underdeveloped, and body fat is often increased.

Diagnosis

During infancy, the diagnosis of PWS may be suspected if poor muscle tone, feeding problems, small genitalia, or the unique facial features are present. If an infant has these features, testing for PWS should be performed. This testing should also be offered to children and adults who display features commonly seen in PWS (e.g., developmental delay, uncontrollable appetite, and small genitalia). There are several different genetic tests that can detect PWS. All of them can be performed from a blood sample.

Methylation testing detects 99% of the cases of PWS. It can detect the absence of the paternal genes that should be normally active on chromosome 15. Although methylation testing can accurately diagnose PWS, it cannot determine whether the PWS is caused by a deletion, maternal uniparental disomy, or a mutation that disrupts imprinting. This information is important for genetic counseling. Therefore, additional testing should be performed, depending on initial findings.

Chromosome analysis, also called karyotyping, can determine whether the PWS is the result of a deletion in the q arm of chromosome 15. It involves staining the chromosomes and examining them under a microscope. In some cases, the deletion of material from chromosome 15 can be easily seen. In other cases, further testing must be performed. FISH (fluorescent in situ hybridization) is a special technique that detects small deletions that cause PWS.

QUESTIONS TO ASK YOUR DOCTOR

- Please explain the genetic basis for Prader-Willi syndrome.
- What are the most serious medical problems associated with this disorder?
- What changes in a person's lifestyle, if any, will help in the treatment of his or her Prader-Willi syndrome?
- What is the prognosis for a person diagnosed with this condition?

More specialized DNA testing is needed to detect maternal uniparental disomy or a mutation that disrupts imprinting. This DNA testing identifies unique DNA patterns in the mother and father, which are then compared with the DNA from the child with PWS.

PWS can be detected before birth if the mother undergoes amniocentesis testing or chorionic villus sampling (CVS). This testing would only be recommended if the mother or father is known to have a chromosome rearrangement or if they already have a child with PWS syndrome.

Treatment and management

There is currently no cure for PWS. Treatment during infancy includes therapies to improve muscle tone. Some infants with PWS also require special nipples and feeding techniques to improve weight gain.

Gene editing research reveals the possibility to correct the problem of hidden genes not being read by cells. CRISPRon/off is one such method that can genetically edit DNA through epigenetic modification. By targeting the gene, small pieces of RNA can guide treatment to the target and remove methyl groups from specific genes to modify their expression.

Treatment and management during childhood, adolescence, and adulthood is typically focused on weight control. Strict control of food intake is vital to prevent severe obesity. In many cases, food must be made inaccessible. This may involve unconventional measures, such as locking the refrigerator or kitchen cabinets. A lifelong restricted-calorie diet and regular exercise program are also suggested. Unfortunately, diet medications have not been shown to significantly prevent obesity in PWS. However, growth hormone therapy has been shown to improve the poor muscle tone and reduced height typically associated with PWS.

In 2021, a study reported on success with intranasal oxytocin to help young boys with a subset of PWS (DEL15) with positive effects on social behavior and eating. The hormone oxytocin plays an important role in food intake, energy expenditure, and controlling body weight.

Special education may be helpful in treating developmental delays and behavior problems. Individuals with PWS typically excel in highly structured environments. PWS varies greatly from one individual to another, including need for behavioral and psychological treatments.

Prognosis

Life expectancy is normal, and the prognosis good if weight gain is well controlled.

Preimplantation genetic diagnosis

Definition

Preimplantation genetic diagnosis (PGD or PIGD) is general term for the techniques used for the genetic profiling of embryos prior to implantation, or of the oocytes before fertilization.

Description

Preimplantation genetic diagnosis (PGD) is used during in vitro fertilization (IVF) to screen for genetic disorders prior to pregnancy in order to avoid implanting embryos that carry inherited disease. It is also used for selective pregnancy termination. PGD is considered an assisted reproduction technique (ART). PGD analyzes the DNA of unfertilized oocytes and fertilized embryos to select ones that meet certain criteria that improve the chances of a normal pregnancy. PGD techniques are normally used before continuing with an IVF program when chromosomal or genetic disorders occur in the family of one of the parents. This can ensure that such diseases will not be passed on in children produced from the IVF process.

Application

The first successful sex identification in blastocysts was performed in 1967 by Robert Edwards and Richard Gardner, and in 1989 the first successful births from human IVF trials were documented. PGD was used to determine the sex of the embryos used in pregnancies where the parents were carriers of X-linked disorders. Sex discrimination is important for those concerned with avoiding sex-linked disorders, but PGD can also be used to help families prepare for sex-dependent parenting or for “family balancing” when previous children are of all one gender. The latter are not considered to be medical reasons, and the ethical nature of this use of PGD is often questioned.

Couples who are carriers for monogenic disorders and are concerned about passing on disease to their future children can use PGD to identify embryos that are free of disease and use only these in IVF attempts. In cases of

KEY TERMS

Assisted reproductive technology (ART)—Medical technologies or procedures that are used during fertility treatments.

Blastocyst—An early developmental stage of a developing embryo.

DNA polymerase—An enzyme that is required for DNA replication. It functions in the addition of new nucleotides in the production of new DNA strands.

Embryo—The multicellular, developing fertilized egg of a vertebrate animal.

Eugenics—The improvement of human genetic features through the use of selective breeding or technologies that allow for genetic selection on the cellular level.

Genetic mosaicism—A mixture of cells of two or more genotypes.

In vitro fertilization (IVF)—The manual combination of egg and sperm cells in a laboratory dish to create a fertilized egg that can be implanted into a woman’s uterus. IVF is an assisted reproductive technology (ART).

Monogenetic disorder—A disorder or disease that is caused by a mutation or defect in one gene.

Oocyte—An immature ovum or egg produced during female gametogenesis.

Polar bodies—A small haploid cell that is formed during oogenesis (creation of an ovum), but that generally does not have the ability to be fertilized.

high-risk pregnancies or where embryo survival is a concern, PGD can help assess the quality of embryos that will be implanted to ensure better chances of the pregnancy leading to live births.

Predisposed cancer syndromes can be screened for such as the BRCA genes, which can contribute to hereditary breast and ovarian cancers. Additionally, HLA (human leukocyte antigen) matching may be used to allow for a second child to match that of a sick sibling. In such cases the cord-blood stem cells from the matched infant can be used to treat the disease of the sibling. Children born as a result of HLA matching through PGD are often called “savior siblings.”

Techniques used in PGD

Techniques that are used in fertility treatment are called assisted reproductive technology (ART). Along

with PGD, other ART can include controlled ovarian stimulus with hormones, transvaginal ultrasound used in oocyte retrieval, and oocyte fertilization with injected sperm DNA. PGD can be performed on embryos at different stages of development, but the common stages are:

- Unfertilized oocytes
- Fertilized embryos and polar bodies
- Three-day cleavage-stage embryos
- Blastocyst

Analysis of oocytes and early-stage embryos can only reliably test maternal contributions to the embryo. PGD of these cells can inform on X-linked disorders and anything else that may be inherited only from the mother. At later stages of embryo development the genetics from both parents can be assessed.

Fluorescent in situ hybridization (FISH)

FISH is used to detect chromosomal abnormalities in the embryo, and unlike karyotyping it can be used on interphase chromosomes, which are much less dense and compact. Fluorescent probes made from short sequences of DNA bind to complementary sequences on sample

DNA from the embryo. When the samples are exposed to particular wavelengths of light, the probes will fluoresce. If the probes bind to genes or sequences that are specifically present in certain genetic disorders, the embryo genome can be quickly analyzed for the occurrence of those genetic abnormalities.

Polymerase chain reaction (PCR)

Kary Mullis developed PCR in 1985 as a way to replicate DNA in vitro. Using thermo-stable DNA polymerases, sequences of DNA can be amplified artificially from a small amount of template DNA to produce many copies of a single sequence that can be used for further analysis. In PGD, PCR is used to amplify embryo DNA at particular sites that are associated with known disorders so that it can be further analyzed for any abnormalities.

Risks of PGD

While highly effective in assessing the genetics of embryos and helping parents at risk of passing genetic disorder on to their children, PGD is an invasive process that can damage the embryo during biopsy. Additionally,

cryopreserved embryos have a 20% chance of not surviving the thawing process, and there is some evidence that biopsied embryos have an even lower rate of survival after cryopreservation. In mouse models, offspring produced from biopsied embryos showed risks of weight gain, memory loss, and brain alterations that have been associated with neurological disorders like Down syndrome and Alzheimer's.

Analysis of PGD assumes the outcome of a biopsy of one cell is representative of a multi-cell embryo; however, the occurrence of genetic mosaicism could result in false positives or negatives, and this could lead to either normal embryos being discarded or the acceptance of abnormal embryos, respectively.

Ethics

There are conflicting opinions on the social acceptability of PGD due to its implicated contributions to eugenics. In some countries PGD is only permitted for the prevention of stillbirths and genetic diseases. Sex selection is often not considered acceptable for reasons that are not medically related. Forms of social selection like “family balancing,” when there are multiple children of one sex and parents would like a child of the opposite sex, or selection that discriminates against disabilities or intersex traits are not always considered appropriate reasons to pursue PGD.

Those that argue for wider usage of PGD state that parents have a moral obligation to select in favor of any traits that may give their future children the best life possible, including selecting for genetic traits like intelligence and beauty.

Advocates for disabled communities believe that PGD discriminates against their disabilities, while some communities argue for the use of PGD to select embryos with the traits associated with their disability.

In cases where parents explore ART to provide a cord-blood donation from a “savior sibling” to treat an existing sick child, there are questions about the ethical nature of how this exploits the unborn child who would be conceived with the intent of providing treatment for their sibling.

Policy

PGD is widely used, but many countries do not allow sex selection for nonmedical reasons. The legality and policies on ART varies from country to country.

- **Canada:** In 2012 budget cuts removed the 2004 Assisted Human Reproductive Act, and PGD became unregulated at the national level, allowing provinces to

QUESTIONS TO ASK YOUR DOCTOR

- I am/my partner is a carrier for an autosomal recessive disorder. How will PGD determine the outcome for my pregnancy?
- What other decisions can we make about the genetics of the embryos using PGD?
- What are the ethical codes and legal policies that regulate ART where I live?
- What risks are associated with ART?

make rulings about how the technology was used on their own.

- **Germany:** Since 2011 PGD is allowed only in certain cases (i.e., when there is a high instance or likelihood of stillbirth or inheritance of genetic diseases).
- **India:** PGD is regulated under a 1994 act that prohibits its use for sex selection.
- **United Kingdom:** Reproductive clinics are required to have a license if they provide PGD. A regulatory agency requires the clinics to submit an application so that the suitability of the genetic test being requested can be reviewed. The regulatory agency prohibits sex selection for social or cultural reasons, allowing it only for the identification for sex-linked disorders. This includes intersex variations, which some gender advocacy groups say is unethical.
- **United States:** There is no uniform regulation of the use of PGD on the national level and it usually falls under state law or professional guidelines. The Centers for Disease Control and Prevention (CDC) requires IVF clinics to report annual pregnancy success rates to the federal government, but this reporting does not include the use of PGD. The American Society for Reproductive Medicine states that PGD should not be used solely for sex selection.

Prenatal ultrasound

Definition

Prenatal ultrasound is a procedure performed during pregnancy to obtain images of the fetus.

Description

A prenatal ultrasound, also known as a sonogram, is a procedure in which a tool called a transducer is placed on a woman’s abdomen so that images of the fetus in the woman’s uterus can be viewed on a monitor. The most commonly used ultrasound produces a two-dimensional image of the fetus, although the technology exists to create a three-dimensional image as well. Electrical energy coming in to the transducer is converted to high-frequency sound waves. The sound waves reflect off of any structures they contact and return to the transducer and are converted back to electrical energy. Generally, more dense structures, like fetal bones, are seen as bright white images on the screen. Less dense tissue, like organs and fluid, shows darker on the screen. Gel placed on the woman’s abdomen acts as a medium and allows for more rapid transmission of the sound waves and a better image.

There are many reasons an obstetrician may recommend an ultrasound for a pregnant woman. Some of these reasons include getting an accurate gestational age (dating) of the pregnancy, determining viability of a fetus (i.e., heartbeat), determining if any structural changes are present in the fetus, and determining if there are problems in the fetal environment. A prenatal ultrasound is performed by a healthcare professional, including an obstetrician, a radiologist, and a maternal-fetal medicine specialist. The American Institute of Ultrasound Medicine recommends that physicians performing ultrasound complete an approved residency program, a fellowship, or postgraduate training that includes three months and 500 supervised ultrasound procedures. An ultrasound technician often performs the initial measurements and, if needed, the physician reviews the procedure and obtains additional images. Ultrasounds are sometimes referred to as either basic (level 1) or comprehensive (level 2 or 3), depending on the quality of the equipment used, the amount and detail of the fetal anatomy studied, and the training of the person performing the procedure.

Most pregnant women in the United States have one prenatal ultrasound. There is some debate about when this ultrasound should take place. Early ultrasounds, in the first trimester of pregnancy, are the most accurate way to determine how far advanced a pregnancy is and to set an accurate due date. However, these early ultrasounds do not allow for a detailed study of the fetal anatomy for any changes in development. An anatomical study of the fetus is best performed at about 18–20 weeks gestation. Women who are at increased risk for birth defects, genetic conditions, or pregnancy complications may have multiple ultrasounds. Studies have shown, and the American Institute of Ultrasound Medicine Bioeffects Committee has concluded, that there is no association between prenatal ultrasounds using sound waves and an increased chance for birth defects or other pregnancy complications. Studies have also shown that there is significant psychological benefit to parents from having ultrasounds performed. Prenatal ultrasounds provide parents with reassurance that the fetus is developing normally or identify problems that can be investigated further.

First-trimester ultrasounds

The first trimester of pregnancy is considered to be the first 12 weeks of pregnancy, or the first three months. Prenatal ultrasounds in the first trimester may be performed either on the abdomen or vaginally; however, to get the clearest images in the first trimester, a vaginal ultrasound is performed. In this type of ultrasound, a smaller transducer is placed into the vagina, up to the

A doctor performs a 3-D ultrasound on a pregnant woman. (*Marius Pirvu/Shutterstock*)

cervix. By having the transducer closer to the uterus, the fetus, which is very small in the first trimester, can be viewed more clearly.

First-trimester ultrasounds are often performed for women, unsure of the dating of their last menstrual period, who want to determine the correct gestational age. Early ultrasounds are best for dating because, early in a pregnancy, all fetuses grow at about the same rate. Therefore, measurements correspond well to gestational age. However, later in pregnancy, fetuses show more characteristics of their own growth pattern, and correlation to gestational age is not as clear. In general, first-trimester ultrasound measurements of gestational age are accurate to within about five days. Second-trimester ultrasound measurements of growth are accurate to about 8–12 days. Pinpointing a correct gestational age aids in determining an accurate due date and, consequently, in scheduling the proper tests at the proper times. One test that is offered to all pregnant women is called a maternal serum multiple marker screening test. This test screens a pregnancy to determine if there is an increased chance for Down syndrome, open spine defects, and another chromosomal condition called trisomy 18. This test can be performed between 15 and

20 weeks of pregnancy, and may result in a false-negative or false-positive result if the due date of the pregnancy is not accurate.

First-trimester ultrasounds can also be used to detect multiple pregnancies, ectopic pregnancies (pregnancies located outside of the uterus), and the location of the placenta. The placenta is the organ between the mother and fetus that allows for the crossing of nutrients and oxygenated blood. Sometimes the placenta is located over the cervix, blocking the path the fetus would normally take to exit the uterus. Complications of this condition, called placenta previa, can be avoided by performing a cesarean section rather than a vaginal delivery. Another common reason for a first-trimester ultrasound is vaginal bleeding. First-trimester ultrasounds may be able to detect a pregnancy loss or a pregnancy that is not progressing normally. In general, the fetus is too small in the first trimester to view the anatomy in detail. However, a few serious structural changes to the fetus can be identified in the first trimester. These include conditions like anencephaly (a condition in which the fetal brain and skull does not develop), cystic hygromas (large fluid-filled sacs around the fetal neck), and conjoined twins.

Nuchal translucency

First-trimester ultrasounds can also be used to screen a pregnancy for chromosomal conditions, including Down syndrome. People with Down syndrome have mild to moderate intellectual disabilities, a characteristic facial appearance, an increased chance for heart defects and other structural changes, and short stature. By measuring the translucent, or fluid-filled, area at the back of the fetal neck, it can be determined if there is an increased chance for a chromosomal change. An increased nuchal translucency indicates an increased chance for a chromosomal change. This measurement, in combination with an analysis of two proteins in the mother's blood called beta-hCG (human chorionic gonadotropin) and pregnancy-associated plasma protein A (PAPPA) in the first trimester of pregnancy, is referred to as first-trimester screening for aneuploidy (changes in chromosome number).

By performing a first-trimester screening between ten and 14 weeks of pregnancy, about 80% of fetuses with Down syndrome can be detected. Most fetuses with two other chromosomal conditions, trisomy 13 and 18, can also be detected by first-trimester screenings. Therefore, first-trimester screening for aneuploidy is considered as effective as the more traditional screening for aneuploidy performed in the second trimester. However, the American College of Obstetricians and Gynecologists recommended that individuals who perform prenatal ultrasounds and take measurements of the nuchal translucency complete additional training to ensure that they are taking this measurement correctly. The recommendation also stated that there should be ongoing monitoring of the accuracy of this measurement, that appropriate counseling about screening and testing options for aneuploidy should be provided to women wishing to have first-trimester screening, and that the screening should only be performed when further diagnostic testing indicates an increased risk for aneuploidy. The diagnostic test for chromosomal changes available in the first trimester of pregnancy is called a chorionic villus sampling (CVS). This test can be performed between ten and 12 weeks of gestation. However, CVS is not as commonly available as amniocentesis, the second-trimester test for chromosomal changes.

Screening for aneuploidy in the first trimester is a more recent event and allows women to have diagnostic testing earlier and to make decisions about continuing or discontinuing a pregnancy earlier. Ending a pregnancy in the first trimester or early second trimester is safer for the mother than later pregnancy terminations. In fetuses with an increased nuchal translucency and normal chromosomes, follow-up ultrasounds are recommended as

heart defects, other structural changes in development, and other genetic syndromes can still be present.

Second-trimester ultrasound

Ultrasounds in the second trimester of pregnancy are most often performed using the transducer on the maternal abdomen. Vaginal ultrasound may be used in situations where there is a problem with good visualization of the fetus, such as in obese women. In the second trimester, the fetus is larger, and it is possible to see more detail of the development of the fetal anatomy. Anatomy scans of the fetus are most often performed at 18–20 weeks of gestation and can also include images of the placenta, amniotic fluid, umbilical cord, and the sac containing the fetus.

It is also important to look for fetal movement. The absence of movement can indicate the presence of a condition affecting the muscles, bones, or central nervous system. There are many other fetal anomalies that can be detected as well. The finding of a structural anomaly often increases the chance for aneuploidy. Patients may be offered additional tests for more information. When one fetal anomaly is noted on ultrasound, it is important to study the fetus carefully for the presence of other anomalies, since anomalies often occur simultaneously. The prognosis for a fetus when an anomaly is found depends on the severity of the anomaly, the presence of other anomalies, and the presence of a chromosomal condition. Fetuses with mild isolated anomalies have the best prognosis.

Fetal anomalies

A detailed second-trimester ultrasound allows for the identification of structural changes in development, which, in themselves, may be a significant concern, or may be a sign that additional problems like chromosomal changes are present. About 2%–3% of all live-born infants have a birth defect.

A detailed ultrasound studies many structures in the fetal head and brain. There is a measurement of the amount of fluid in the ventricles, or areas, of cerebrospinal fluid in the brain. Too much fluid in the ventricles of the brain is a condition called hydrocephalus. Depending on the degree of hydrocephalus, there can be underdevelopment of the brain and severe intellectual disability. The presence of the two main lobes of the brain and the skull are noted to rule out a type of open spine defect called anencephaly. The lobes of the brain are studied to detect midline defects of the brain such as holoprosencephaly, in which the lobes of the brain have not divided properly. The cerebellum, an organ at the back of the brain, is studied because changes in the shape of the cerebellum or the

bones in the front of the skull are indicative of an open spine defect, or spina bifida. The size of the head is measured, because a small head size, called microcephaly, can result in intellectual disability. The face is studied for the presence of a cleft lip, a small jaw, or either widely or narrowly spaced eyes.

A study of the fetal chest and abdomen will determine if the organs are located on the normal side, or if they are reversed. Ultrasound can detect the presence of diaphragmatic hernia, in which there is a hole in the diaphragm and the intestines are herniated through it into the chest. Abdominal wall defects, in which there is an opening in the abdomen and the intestines are located outside the body, can be detected. Changes to the kidneys, such as cystic or missing kidneys, and cystic malformations of the lungs, can be detected. The heart is a particularly complex organ and can be difficult to study with ultrasound. The more severe heart defects can be identified with ultrasound, but many smaller structural changes to the heart are missed with ultrasound. When a heart defect is suspected, a more specialized ultrasound of the fetal heart, called an echocardiogram, can be performed. Ultrasound evaluation should also include views of the fetal bladder and stomach. The sex of the fetus can often be seen after 18 weeks of gestation.

A careful study of the fetal spine can detect the presence of spina bifida. Changes in the bones of the arms and legs can also be noted. In particular, an inward curving of the feet or club feet can be seen as well as missing limbs. Shortened or curved long bones are a sign of a skeletal dysplasia. There are many types of skeletal dysplasias with varying degrees of severity. Some skeletal dysplasias also include broken bones, short ribs, or changes to the bones in the spine.

Not all changes in development can be detected by ultrasound. The detection rate for individual anomalies with ultrasound varies, and centers that perform ultrasound should collect their own data before providing statistical detection rates to patients. In addition, there can be instances when a condition is diagnosed by ultrasound, but not truly present, or when a condition is misdiagnosed. Patients should be informed of the limitations of ultrasound before the procedure is performed.

Ultrasound markers

With the advancement of ultrasound technology, additional findings on ultrasound have been identified. These findings are not anomalies, or structural changes, that in themselves cause any problem in development. However, these findings have been associated with an increased chance for chromosomal changes in a fetus. Therefore, these findings have been referred to as markers,

or soft signs, of aneuploidy. For instance, fluid-filled cysts called choroids plexus cysts have been seen in fetuses with aneuploidy. The finding of a marker alone in a woman with no other increased risk for aneuploidy is not likely to be significant. Finding multiple markers does increase the chance for aneuploidy. When a marker is seen in the fetus of a woman at increased risk for aneuploidy based on advanced maternal age, maternal serum multiple marker screening, or family history, the patient should receive additional genetic counseling to discuss the finding and how it affects the risk for aneuploidy and the additional testing options. When not associated with aneuploidy, these markers are most often of no significance to the health of the fetus.

Fetuses with several chromosomal conditions can survive to full term. Those conditions include trisomy 21 (Down syndrome), trisomy 18, trisomy 13, and Turner syndrome (45,X).

About half of children with Down syndrome have a heart defect, some of which can be detected by ultrasound. In addition, fetuses with Down syndrome may have various gastrointestinal changes or a cystic hygroma (fluid-filled cyst around the neck) that may be detected by ultrasound. Ultrasound markers for Down syndrome include inward curving of the fifth finger, an increase of fluid in the kidney, short long bones in the upper arm or leg, extra skin at the back of the neck, a bright spot in either the heart or bowel, absence of the nasal bone, and fluid-filled cysts in the brain. When any of these findings is seen in a woman with an increased chance for Down syndrome, her risks may be increased. If an ultrasound is performed in a woman with an increased risk for Down syndrome, and none of these findings is seen, her risks may be lower than previously estimated. Risk reduction based on ultrasound is controversial and should not be done unless an ultrasound center has collected their own data on detection of Down syndrome with ultrasound.

Trisomy 18 is a rare, severe condition caused by the presence of an extra chromosome 18. Babies with trisomy 18 have severe neurological problems and intellectual disability and usually do not survive more than a few months. The most common ultrasound findings in fetuses with trisomy 18 include heart defects and skeletal changes. Fetuses with trisomy 18 have a characteristic hand position that can be noted, clubbed feet, an unusual shape to the feet called rocker-bottom feet, and an unusual shape to the skull called a strawberry-shaped skull. Many other anomalies of other organs have also been noted in fetuses with trisomy 18, including diaphragmatic hernia, open spine defects, and significant growth delay. Markers for trisomy 18 include a thickened nuchal fold, extra fluid in the kidneys, choroids plexus cysts, and a single umbilical artery. Most, but not all,

KEY TERMS

Aneuploidy—A change in the number of chromosomes present, so that there are additional or missing chromosomes.

Cystic hygroma—An accumulation of fluid around the head and neck caused by the blockage of drainage of lymphatic fluid.

Diaphragmatic hernia—A defect that occurs when the diaphragm does not close properly, and the intestines are able to be herniated through the diaphragm into the chest cavity.

Gestational age—An estimation of the age of a pregnancy. The beginning of gestation or pregnancy is counted from the first day of the woman's last menstrual period, although conception usually takes place about two weeks later.

Holoprosencephaly—A malformation of the brain in which the two hemispheres or lobes of the brain do not separate properly.

Hydrocephalus—The presence of extra cerebrospinal fluid in the ventricles of the brain.

Neural tube defect—A defect in closure of the bones of the spine or skull; defects of the brain and skull are called anencephaly, while defects of the spine are called spina bifida.

fetuses with trisomy 18 will have some feature of the condition identified on ultrasound.

Trisomy 13 is also a rare, severe condition caused by the presence of an extra chromosome 13 and associated with multiple birth defects, intellectual disability, and a shortened lifespan. Ultrasound findings in fetuses with trisomy 13 include heart defects, brain malformations like holoprosencephaly, small head size, cleft lip, kidney malformations, extra fingers or toes, and growth delay. Markers for trisomy 13 include an increased nuchal fold and a bright spot in the heart. Most, but not all, fetuses with trisomy 13 will have a feature of the condition noted on ultrasound.

Turner syndrome is a condition in which a female is missing the second X chromosome. Females born with Turner syndrome have an increased chance for heart defects and kidney problems. Girls with Turner syndrome have short stature and will experience infertility as adults. Many pregnancies of fetuses with Turner syndrome miscarry. Ultrasound appearance of these pregnancies often includes a large cystic hygroma and generalized fluid accumulation throughout the fetal body, called hydrops

or edema. Fetuses with Turner syndrome that survive to delivery will sometimes show heart defects, kidney problems, or a cystic hygroma on an ultrasound.

Another way to study fetal well-being is to study the fetal environment and associated pregnancy structures. If a fetus has oligohydramnios (a low amount of amniotic fluid) in the sac surrounding it, the lungs may not develop and the fetus may not survive. Oligohydramnios may occur because of absence of the kidneys, other structural defects, or due to a rupturing of the membranes or sac surrounding the fetus. Polyhydramnios (an excess of amniotic fluid) may also be a sign of structural changes, especially blockages in the urinary tract system, and can lead to premature delivery of a fetus. There can also be problems when the inner membrane of the sac that holds the fetus tears. The torn strands of amnion can wrap around the fetus and cut off blood flow to those areas. The presence of amniotic bands can disrupt the formation of limbs or any structure they wrap around and cause deformations that range from mild to lethal. There can be problems with the umbilical cord if the cord is too long or too short, has knots in it, is entangled around the fetus, has cysts in it, or is not inserted into the center of the placenta. The placenta may also cause or be associated with problems if it is too small, too large, split, located over the cervical opening, detaches from the uterus, or has tumors in it. Molar pregnancies occur when the placenta is swollen and cystic and no fetus is present. In a partial molar pregnancy, a small, malformed fetus with a chromosomal abnormality called triploidy is often present. In triploidy, a fetus has a whole extra set of chromosomes, so that the total number is 69 instead of the usual 46.

Third-trimester ultrasound

Ultrasounds in the third trimester, or last three months, of the pregnancy are often done to monitor fetal growth. If a fetus is macrosomic (large), as is often the case in maternal diabetes, then the fetus is monitored for timing of delivery. Some fetal anomalies that are present earlier do not show features until the third trimester, and some fetal anomalies, like hydrocephalus, may not develop until the third trimester. Ultrasound may be used in the third trimester for fetuses with known anomalies to monitor progression and consider delivery techniques and timing.

Another important use of ultrasound is to guide prenatal procedures such as chorionic villus sampling (CVS) and amniocentesis. In CVS, a physician inserts a catheter into the vagina, through the cervix, and into the placental tissue using ultrasound guidance. A small sample of the placental tissue can be obtained for chromosomal studies by suctioning. CVS is performed at 10–12

weeks gestation. Amniocentesis is a test performed at 15–20 weeks gestation to obtain a sample of amniotic fluid from the sac of fluid around the fetus. This fluid contains fetal cells that can be used for chromosomal analysis of the fetus. During amniocentesis, a pocket of amniotic fluid located away from the fetus is targeted. Ultrasound is used to identify a pocket of fluid and to guide the insertion of the needle into the targeted area.

Ultrasound is a useful tool in the care of pregnant women. There are many uses for prenatal ultrasound and no identified risk with the procedure.

Primary ciliary dyskinesia

Definition

Primary ciliary dyskinesia (PCD), formerly known as Kartagener syndrome, refers to a condition that involves difficulty with clearing mucus secretions from the respiratory tract, male infertility, and the abnormal placement of abdomen and/or thoracic organs. Some individuals have situs inversus, in which the placement of organs is a mirror image of their normal placement (e.g., the heart is on the right side instead of the left side).

A researcher uses a transmission electron microscope (TEM) to examine pulmonary cilia, which can be seen in the section of the circular display area at lower left; other samples are seen at lower right. Cilia are hair-like structures that line the lungs and other organs. In the lungs, they should move in a continuous wave to clear mucus, dust, and bacteria from the lungs. In primary ciliary dyskinesia (PCD), the cilia do not function properly, causing respiratory problems. (Pascal Goetgheluck/Science Source)

Description

PCD was first reported by Manes Kartagener (1897–1975), a physician from Switzerland. In the 1930s, Kartagener and a colleague described a familial form of bronchiectasis with situs inversus and nasal polyps. This came to be known as Kartagener syndrome. PCD has also been known as Siewert syndrome, after another physician, A.K. Siewert, who described it in the early 1900s.

At one time, PCD was known as immotile cilia syndrome. That name is no longer used, because of the discovery that the cilia are actually not immotile; rather, their movement is abnormal.

PCD is caused by abnormalities of the cilia that line the respiratory tract and also form the flagella of sperm. Cilia are tiny hair-like structures that contain a bundle of small parallel tubes that form a central core. This core is called the axoneme. Ciliary movement is accomplished by the bending of the axoneme. One of the most

important associated structures that enables ciliary movement to occur is sets of tiny arms that project from each tubule. These tiny arms are called dynein arms.

Cilia line the cells of the lungs, nose, and sinuses. Before reaching the lungs, air travels through the airway, where it is moistened and filtered. The nasal passages and airway are lined with mucus membranes. The mucus covering the mucus membrane traps dirt and other foreign particles that have been breathed in. The cilia lining the membranes move in a wavelike manner, shifting the layer of mucus and carrying away the dirt and debris that has been trapped. This mucus can then be coughed out or swallowed into the stomach.

In PCD, the cilia do not move, move very little, or move abnormally. Because the cilia do not function properly, the mucus is not cleared from the respiratory tract, which leads to sinus infection (sinusitis) and chronic changes of the lung (bronchiectasis), which make it difficult to exhale. Mucus clearance from the middle ear can also be affected, and over time it can lead to hearing loss.

The male infertility in PCD is also caused by abnormal cilia movement. One spermatozoon consists of a head, midpiece, and a tail or flagellum. The tail of a spermatozoon is a long flagellum consisting of a central axoneme. This axoneme enables the movement of the flagellum so that the spermatozoon can propel its way to the fallopian tube and burrow through the egg coat to fertilize the egg. In PCD, these cilia are either immotile or are not able to move normally to complete the journey to the fallopian tubes, nor are they able to burrow through the egg coat. The result is male infertility.

Complete situs inversus involves reversal of both the abdominal and thoracic organs so that they form a mirror image of what is normal. In partial situs inversus, the thoracic organs may be reversed, while the abdominal organs are normally positioned, or vice versa. Approximately 1 in 10,000 adults has situs inversus. Only about 20% of individuals who have complete situs inversus are diagnosed with PCD. For those with complete situs inversus who are diagnosed with PCD, there is only a small risk for associated cardiac defects. Partial situs inversus may occur in individuals who have PCD as well. Partial situs inversus, also called situs ambiguus, has a higher association with other abnormalities, including polysplenia or asplenia (extra or absent spleen) and cardiac defects.

One theory behind the association of situs inversus with the underlying cause of PCD is that the lack of ciliary movement in the developing embryo may result in incorrect organ rotation in approximately 50% of affected individuals. In fact, 50% of patients with PCD will have situs inversus. However, this is a theory supported only by some researchers and remains open to debate.

Genetic profile

PCD is an autosomal recessive condition. In order to have the condition, an individual needs to inherit two copies of the gene for the condition, one from each parent. Individuals who carry only one gene for an autosomal recessive syndrome are called heterozygotes. Heterozygotes for PCD have normal ciliary function and do not have any clinical features of the condition. If two carriers of PCD have children, there is a 25% chance with each pregnancy of having a child with PCD. Prenatal testing and genetic counseling are recommended for those who have a familial history of PCD.

The components that form the cilium contain several hundred different proteins. Each is coded for by different DNA sequences, potentially on different chromosomes. A defect in any of these codes could produce an abnormal or missing protein that is a building block for the cilium and thus could cause abnormal ciliary structure and movement, resulting in PCD. Research shows that about 30% of cases of PCD are caused by mutations in two genes *DNAI1* and *DNAH5*, but changes in at least 40 genes can cause the disorder, and in many other cases the genetic cause is unknown.

X-ray of the lungs of a patient with PCD. One of the signs of this disorder is situs inversus, the inversion of the internal organs. Here, the heart (lower left) and stomach (lower left) and liver (lower right) appear on the opposite side of the body than normal. (Zephyr/Science Source)

When the same condition can be caused by different genetic abnormalities, this is known as genetic heterogeneity. In fact, several different defects in cilia have been seen in association with PCD, including overly long cilia, overly short cilia, absent cilia, and randomly oriented cilia, suggesting genetic heterogeneity. Studies have suggested that the most common defect of cilia in PCD is the lack of dynein arms. There have been rare cases in which individuals have PCD yet have no detectable abnormality of the cilia, even though the ciliary function is abnormal. Results of one study involving a genome-wide linkage search performed on 31 families with multiple individuals affected with PCD strongly suggested extensive heterogeneity. Potential regions involving genes responsible for PCD were localized on chromosomes 3, 4, 5, 7, 8, 10, 11, 13, 15, 16, 17, and 19.

Demographics

PCD occurs in approximately one in 16,000 to one in 30,000 live births, but this range is thought to be an undercount; as the disorder is often misdiagnosed, PCD is more commonly diagnosed in males because of infertility investigations. This genetic disorder does not appear to cause infertility issues in females.

Signs and symptoms

Newborns who have PCD may present with neonatal respiratory distress. Often when individuals are diagnosed with PCD in later childhood, problems such as neonatal respiratory distress may be identified in their history. Symptoms that may present in childhood include recurrent ear infections (otitis media) that can lead to hearing loss, chronic productive cough, reactive airway disease, pneumonia, chronic bronchitis, runny nose (rhinitis) with a thin discharge, and sinus infection (sinusitis). Situs inversus usually does not present symptomatically unless it is associated with a congenital heart defect.

The most common clinical expression of PCD in adults is chronic upper and lower airway disease presenting as sinusitis and bronchiectasis. Clubbing of the digits (fingers) may occur as the result of chronic hypoxia (lack of oxygen) from bronchiectasis. In males of reproductive age, male infertility is almost universal. In females who have PCD, infertility is not usually a characteristic. This difference suggests that the egg transport down the fallopian tube is associated more with muscle contractions than with ciliary movement.

Several other conditions should be considered when the aforementioned symptoms present, including cystic fibrosis (CF), immune deficiencies, and severe allergies. Although the causes of PCD and CF are completely different, the symptoms of these two diseases are very

KEY TERMS

Bronchiectasis—An abnormal condition of the bronchial tree, characterized by irreversible widening and destruction of the bronchial walls of the lungs.

Complete situs inversus—A laterality defect resulting in a mirror image of the normal organ formation with heart, spleen, and stomach on the right side, and the liver and gallbladder on the left.

Cystic fibrosis (CF)—A respiratory disease characterized by chronic lung disease, pancreatic insufficiency, and an average age of survival of 20 years. Cystic fibrosis is caused by mutations in a gene on chromosome 7 that encodes a transmembrane receptor.

Dyskinesia—Impairment of difficulty in performing voluntary movements, usually resulting in jerky or interrupted movements.

Tympanoplasty—Any of several operations on the eardrum or small bones of the middle ear to restore or improve hearing in patients with conductive hearing loss.

similar. Often when the symptoms present, children with PCD are tested for CF first, because the incidence of CF is much higher (one in 2,400). CF is also associated with male infertility.

Diagnosis

Diagnosis of PCD is confirmed by identifying the ciliary abnormalities of structure and movement. This is accomplished by biopsy of the mucus membranes of the respiratory tract and/or by examination of sperm, looking for ciliary dyskinesia. A less invasive way of diagnosing PCD is through the use of high-speed video microscopy. This technique requires special equipment and a high level of training to use. In 2021, it was not widely available. Situs inversus can be identified by x-ray or ultrasound examination. Infertility investigation may elicit the possibility of PCD in a patient who has been previously undiagnosed.

After a diagnosis is made, genetic counseling should be provided to discuss the inheritance pattern, to help identify other possible affected family members, and to discuss reproductive options.

Because PCD is an autosomal recessive disorder, individuals who have had a child with PCD have a 25% chance with each future pregnancy of having another

QUESTIONS TO ASK YOUR DOCTOR

- Please explain what the term “situs invertus” means in regard to my child.
- What is the mechanism by which PCD is inherited?
- What kinds of treatment are recommended for my child’s medical condition?
- Will our family doctor be able to deal with this medical condition, or will we have to see specialists? If so, which ones?

child with PCD. For a couple with a previously affected child, prenatal diagnosis may be possible with an ultrasound examination to identify a fetus who has situs inversus. However, if the fetus does not exhibit situs inversus, it is still possible to have PCD. It is important to remember that identifying a fetus that has situs inversus in a family not known to be at an increased risk for PCD does not mean that the fetus has PCD, because only 20% of individuals who have situs inversus have PCD.

Currently, mutations in 30 different genes have been found to be mutated in PCD. These include *DNAH5*, *CCDC39*, *DNAI1*, *CCDC40*, *DNAH11*, *DNAAF1*, *LRRC6*, *DNAI2*, and *DNAAF2*. However, one-third of patients do not have mutations in these genes.

Treatment and management

Treatment for PCD involves treatment of the symptoms. Treatment for sinusitis includes the use of antibiotics to treat and prevent recurrent infection. Occasionally, surgery to relieve the sinusitis and remove nasal polyps that may be present is necessary. Daily chest physiotherapy to loosen mucus secretions is a common therapy as well, and if started early in life it can help to prevent or delay development of bronchiectasis. Tympanoplasty in children with recurrent ear infections is often necessary.

Advances in reproductive technology allow for men who have PCD to have the opportunity to have children. A procedure called intracytoplasmic sperm injection (ICSI) now allows immotile or dysmotile sperm to fertilize an egg. ICSI involves injection of a single sperm into single eggs in order for fertilization to occur. This procedure first involves ovulation induction and egg retrieval to obtain eggs for an attempt at fertilization by ICSI. In vitro fertilization (ICSI) pregnancy rates vary from center to center. Overall, pregnancy rates utilizing these procedures of 10% to 40% have been quoted worldwide.

The chance of an affected male and his unaffected partner having a child who has PCD is small. If the disease incidence is one in 32,000, then the chance for the unaffected woman to be a carrier of PCD is approximately one in 100, and the chance of having an affected child would be expected to be approximately one in 200 (0.5%). However, all children of affected males or females will be carriers for PCD.

Prognosis

The severity of PCD is variable. With the advent of antibiotic use for infection control, the life expectancy of a patient with PCD is close to or within the normal range if there are no immediate problems in the newborn period.

Clinical trials for diagnosis and treatment of PCD are underway. Participation in a clinical trial is voluntary and at no cost to the participant. All clinical trials receiving U.S. government funding, and some supported by private industry, are posted at <https://www.clinicaltrials.gov>. Foreign trials are listed at <https://www.orpha.net>.

Primary familial brain calcification

Definition

Primary familial brain calcification (PFBC) is an inherited neurodegenerative disorder that results in abnormal deposits of calcium phosphate in the basal ganglia and other regions of the brain. Mutations (changes) in several different genes can result in PFBC, leading to considerable variation in the symptoms of the disorder and their severity. PFBC is frequently referred to as familial idiopathic basal ganglia calcification (FIBGC), which was formerly known as Fahr disease.

Description

PFBC is a very serious neurodegenerative disorder that typically develops in people in their 30s or 40s and progresses gradually. PFBC is characterized by deposits of calcium in the basal ganglia. These are four masses of gray matter (the cell bodies of neurons or nerve cells) that are located deep within each cerebral hemisphere of the brain. Calcium deposits may also develop in other areas of the brain. These deposits can be seen with neuroimaging, such as computed tomography (CT) scans. As the deposits grow and the disorder progresses, neuropsychiatric symptoms and movement problems develop. The neuropsychiatric symptoms often appear first and may be the most serious manifestation of PFBC. These symptoms range from slightly impaired memory and concentration to significant personality and/or behavior changes and even to psychosis and dementia. Migraine headaches are also common in people with PFBC. Movement symptoms may include clumsiness, an unsteady gait, involuntary movements, muscle cramping, fatigue, slow or slurred speech, and difficulty swallowing (dysphagia).

It is not clear exactly why brain calcification occurs or why this results in the observed symptoms. However, more severe signs and symptoms often seem to correlate with greater amounts of calcification. It has been suggested that the calcium deposits interfere with nerve signaling pathways in the brain, especially those pathways that connect the basal ganglia to the frontal lobes that are responsible for reasoning, planning, problem solving, and judgment. Areas of the brain that are involved in mood, motivation, and social behaviors can also be affected.

Genetic profile

In 2015, PFBC had been associated with mutations in four different genes: *SLC20A2*, *PDGFRB*, *PDGFB*, and *XPR1*. These genes produce proteins with very different functions in the body. The *SLC20A2* mutations are

KEY TERMS

Autosomal dominant—A trait caused by a gene located on a chromosome other than the X or Y sex chromosomes that is expressed in preference to the second copy of the same gene.

Basal ganglia—The caudate nucleus, the lentiform nucleus, the amygdala, and the claustrum.

Dystonia—Poor or disordered muscle tone.

Familial idiopathic basal ganglia calcification (FIBGC)—Fahr disease or primary familial brain calcification (PFBC).

PDGFB—The gene that encodes subunit B of the platelet-derived growth factor; a deletion in this gene causes PFBC with leukoencephalopathy.

PDGFRB—The gene that encodes a tyrosine kinase protein called platelet-derived growth factor receptor, beta polypeptide (PDGFRbeta), which is essential for activating signal-transduction pathways in cells; mutations in this gene can cause PFBC.

SLC20A2—The gene that produces a protein called sodium-dependent phosphate transporter 2 (PiT-2), which uses sodium to transport phosphate across cell membranes and is very important for regulating phosphate levels in the body; mutations in *SLC20A2* can result in PFBC.

XPR1A—The gene that encodes a receptor that is involved in exporting phosphate out of cells; mutations in this gene can cause PFBC.

responsible for almost half of all identified PFBC cases. The other mutations appear to be responsible for smaller percentages of cases.

PFBC-associated genes

The *SLC20A2* gene is named for “solute carrier family 20 (phosphate transporter), member 2,” in the solute carrier (SLC) family of genes. *SLC20A2* is located on the short arm (p) of chromosome 8 at position 11.21 (8p11.21). It produces a protein called sodium-dependent phosphate transporter 2 (PiT-2) that uses sodium to transport phosphate across cell membranes. Phosphate is required for many different bodily functions, including metabolism, the production of nucleic acids for DNA, signaling between cells, and fat production. PiT-2 is very important for maintaining phosphate homeostasis—consistent levels of phosphate in the body. About 20 different *SLC20A2* mutations are known to cause PFBC. Most of the PFBC-associated mutations in *SLC20A2*

change single amino-acid building blocks in the PiT-2 protein; these changes make the protein unable to effectively transport phosphate into cells. A large deletion in this gene also has been found to cause PFBC. All of these mutations result in high levels of phosphate in the blood and excess phosphate in the brain that combines with calcium to form calcium phosphate deposits. The *SLC20A2* gene is active (produces protein) in cells throughout the body, but the most PiT-2 protein is produced in the basal ganglia and other brain regions that are affected in PFBC.

The *PDGFRB* gene is located on the long arm (q) of chromosome 5 at position 33.1 (5q33.1). It belongs to two families of genes within the immunoglobulin gene superfamily: the “immunoglobulin-like domain containing” and the “I-set domain containing” families. The *PDGFRB* gene produces a protein called platelet-derived growth factor receptor, beta polypeptide (PDGFRbeta). This protein is a member of a family of proteins called receptor tyrosine kinases that are responsible for transmitting signals into the interior of cells from the cell surface. PDGFRbeta is located in the outer membrane of certain types of cells. It is a receptor for platelet-derived growth factor and is activated when this growth factor binds to it. This binding causes PDGFRbeta to activate signaling pathways made up of other proteins inside the cell. It activates these pathways by adding phosphate groups to the proteins in a process called signal transduction. The signaling pathways activated by PDGFRbeta affect many different cell processes, including growth and cell division (proliferation), cell survival, and cell movement. At least two different mutations in the *PDGFRB* gene can result in PFBC. These mutations change single amino-acid building blocks within the protein, but it is unclear how these changes result in PFBC. Presumably, the mutations alter signaling within the cells. This may cause cells that line the blood vessels in the brain to take in too much calcium, which leads to calcification of the blood vessel linings or an increase in phosphate levels that leads to the formation of calcium phosphate deposits. However, since the *PDGFRB* gene is active throughout the body, it is not clear why these mutations appear to only affect the brain.

The *PDGFB* gene produces the subunit B of the platelet-derived growth factor, the protein that binds to and activates the receptor encoded by the *PDGFRB* gene. Mutations in the *PDGFB* gene probably affect the same signaling pathways as mutations in the *PDGFRB* gene. A deletion has been identified in the *PDGFB* gene that causes PFBC with leukoencephalopathy, a disease that affects the white matter (nerve cell projections called axons) in the brain.

In 2015, researchers identified mutations in the *XPRI* gene in several families affected by PFBC. *XPRI*

produces a protein that is important for exporting phosphate from cells, as well as acting as a receptor for retroviruses. The identified PFBC-associated mutations alter phosphate export. This further suggests that dysregulation of phosphate levels may be involved in the development and progression of PFBC.

Inheritance pattern

PFBC is inherited as an autosomal dominant trait. This means that a single copy of a mutated PFBC-associated gene inherited from one parent is sufficient to cause the disorder, even if the corresponding gene inherited from the other parent is normal. Most people with PFBC have one parent who was affected by the disorder. Each child of a PFBC-affected individual has a 50% chance of inheriting the mutation and developing the disease. PFBC-causing mutations may also arise *de novo* (called sporadic or somatic mutations); that is, neither parent carried the mutated gene or was affected by PFBC. However, it is not known how often *de novo* mutations occur.

Demographics

PFBC is believed to be rare, with only about 60 affected families reported in the medical literature. However, since sophisticated imaging of the brain is required to detect calcium deposits, it is likely that PFBC is underdiagnosed or misdiagnosed as a different disorder that causes similar symptoms. Thus, it is likely that there are many more families affected by PFBC.

Signs and symptoms

Signs and symptoms of PFBC most often develop in the fourth decade of life. The severity of the disorder varies considerably. A few affected people have no symptoms related to brain calcification, whereas others have severe psychiatric and movement difficulties. Symptoms also can include migraines and seizures. This variability in symptoms may be a reflection of the different genes and the different mutations in each gene that can result in PFBC.

It is estimated that 20%–30% of people with PFBC have psychiatric and behavioral symptoms, including the following:

- concentration problems
- memory loss
- personality changes
- psychosis (a distorted view of reality)
- dementia (a decline in cognition or intellectual functioning)

Movement symptoms include the following:

- involuntary muscle contractions or tensing (dystonia)
- poor coordination (ataxia)

QUESTIONS TO ASK YOUR DOCTOR

- How is PFBC diagnosed?
- Should I have genetic testing for PFBC? Should my family members be tested?
- What are the chances that I will pass PFBC on to my children?
- Is prenatal testing available for PFBC?
- What is the prognosis for a person diagnosed with PFBC?

- uncontrolled limb movements (choreoathetosis)

Diagnosis

Diagnosis of PFBC is based on the following:

- neuroimaging with CT scans that shows calcification of the basal ganglia on both sides of the brain (bilateral)
- progressive neurologic dysfunction
- absence of other causes for the symptoms, such as a metabolic disorder, infection, exposure to toxins, or brain trauma
- a family history of PFBC exhibiting autosomal dominant inheritance (a parent with the disorder)

Magnetic resonance imaging (MRI) or x-rays of the brain can also detect calcification. Rarely, patients with symptoms and from families with PFBC have no signs of calcification on brain imaging.

Genetic testing is available for mutations in the *SLC20A2* gene, although these mutations account for only about 40% of cases. In some instances in which no known gene mutation has been identified but at least two family members of different generations are affected by PFBC, a type of test called linkage analysis may be available. Prenatal testing is available for families in which a PFBC-associated mutation has been identified.

Treatment and management

There is no standard treatment for PFBC; rather, treatments are aimed at specific symptoms. Patients usually have annual neurologic and neuropsychiatric assessments. Drug treatments include the following:

- medications for treating anxiety, depression, and obsessive-compulsive behaviors
- medications for tremors, dystonia, or other movement disorders, although levodopa is usually not effective for Parkinsonian-like symptoms caused by PFBC

- antiepileptic drugs for seizures
- oxybutynin or other anticholinergic drugs for urinary incontinence (lack of bladder control)
- migraine drugs for both prevention and treatment of headaches

Prognosis

PFBC has a poor prognosis. It is a progressive disorder without a cure, meaning that the symptoms will gradually increase in their severity.

Primordial dwarfism

Definition

Primordial dwarfism (PD) refers to a group of very rare genetic disorders marked by severe proportionate dwarfism. The term "primordial" means that the disorder begins during the earliest stages of embryonic life, as distinct from having its onset in later stages of development. "Proportionate" means that all the parts of the person's

body are smaller or shorter than normal, in contrast to disproportionate dwarfism, in which the head is significantly larger than the rest of the body, or the trunk is of average size but the limbs are disproportionately large or long. Children diagnosed with primordial dwarfism are extremely small for their age even as fetuses.

There are about 200 different types of dwarfism that had been identified, including primordial dwarfism. Most types of dwarfism are caused by disorders of the endocrine system or the skeleton; all known subtypes of primordial dwarfism, however, are caused by mutations in a number of different genes.

Description

There are five major subtypes of primordial dwarfism commonly recognized by researchers. The number of genetic syndromes considered to represent primordial dwarfism is constantly changing, however, as a result of advances in research and reports of new cases of PD. It is possible that the current classification will undergo further revision. In addition to the fluidity of classifying PD, some individuals are difficult to assign to any of the five recognized subtypes and so may be diagnosed simply as having primordial dwarfism not otherwise specified (PD-NOS).

The five subtypes of PD recognized by geneticists are as follows:

- **Microcephalic osteodysplastic primordial dwarfism type 1 (MOPD1):** This subtype of primordial dwarfism is characterized by microcephaly (an abnormally small head), intellectual disability, and other neurological abnormalities. Most patients die in early childhood. This form of PD has a number of alternate names, including Majewski osteodysplastic primordial dwarfism type 1, after the Polish researcher who described several cases in 1976; cephaloskeletal dysplasia; Taybi-Linder syndrome; and low-birth-weight dwarfism with skeletal dysplasia. MOPD1 is an example of the changes in PD classification: at one time researchers thought they had identified a form of PD that they labeled MOPD type 3, but the present consensus holds that MOPD type 1 and MOPD type 3 are the same entity.
- **Microcephalic osteodysplastic primordial dwarfism type 2 (MOPD2):** As in MOPD type 1, children with this form of PD have abnormally small heads, but they also have distortions of the shape of the pelvis, disproportionately short forearms and legs in early childhood, and severely retarded growth after, as well as before, birth. Other names for MOPD type 2 include Majewski osteodysplastic primordial dwarfism type 2. Persons with this subtype of PD have been reported to live into adolescence or their early 20s.

Charlotte Garside, a five-year-old girl with primordial dwarfism, is held by her mother. She stands just 68 centimeters tall (a little more than two feet) and weighs less than nine pounds. (Kippa Matthews/Barcroft Media/Getty Images)

- **Meier-Gorlin syndrome (MGORS):** Also known as ear, patella, short stature syndrome (EPS) and microtia, absent patellae, micrognathia syndrome, MGORS is characterized by unusually small ears (microtia), the absence of kneecaps in the knee joint, and an underdeveloped jaw (micrognathia). Children with this form of PD usually have normal intelligence and may live into their early 20s.
- **Seckel syndrome (SCKL):** Seckel syndrome is a very rare type of PD characterized by microcephaly, a narrow bird-like face with a nose resembling a bird's beak, and severe intellectual disability. It is also known as bird-headed dwarfism, Virchow-Seckel dwarfism, and nanocephalic dwarfism. The syndrome is named for Helmut Paul George Seckel, who first reported on a case series of the syndrome in 1960.
- **Silver-Russell syndrome (SRS):** Known as Russell-Silver syndrome in the United Kingdom, SRS is characterized by extreme intrauterine growth retardation, very low birth weight, feeding difficulties, failure to thrive, persistent vomiting, a deformity of the little finger known as clinodactyly, and various facial deformities that include a triangle-shaped face. About half of SRS patients have learning disabilities, with the other half being of normal intelligence. SRS was first identified in 1953.

Genetic profile

All known forms of PD are inherited in an autosomal recessive pattern, which means that the person must

inherit a defective gene from both parents. PD affects males and females equally.

- **MOPD type 1:** MOPD type 1 is caused by mutations in the *RNU4ATAC* gene on the long arm of chromosome 2 at 1q14.2. It is not yet clear, however, how mutations in this gene lead to the characteristic features of MOPD type 1.
- **MOPD type 2:** MOPD type 2 is caused by a mutation in the *PCNT* gene on the long arm of chromosome 21 at 21q22.2. The gene codes for a protein called pericentrin, which is important in the process of cell division and multiplication. A mutation in the *PCNT* gene leads to impaired cell division, a reduction in the total number of cells, and the overall short stature and delayed growth characteristic of MOPD type 2.
- **Meier-Gorlin syndrome:** MGORS can be caused by mutations in any one of several genes involved in the pre-replication complex, which regulates the copying (replication) of DNA before cells divide. The specific genes associated with Meier-Gorlin syndrome include *ORC1* on chromosome 1 at 1p32.3, *ORC4* on chromosome 2 at 2q22, *ORC6* on chromosome 16 at 16q12, *CDT1* on chromosome 16q, and *CDC6* on chromosome 17 at 17q21. Researchers are still unsure as to why these mutations lead to the characteristic features of MGORS, although some think that the mutations slow down the process of cell division, which in turn leads to slow growth of the bones and other tissues during the child's prenatal development.
- **Seckel syndrome:** Seckel syndrome may result from mutations in any of six different genes: the *ATR* gene on chromosome 3 at 3q23, the *RBBP8* gene on chromosome 18 at 18q11.2, the *CEP152* gene on chromosome 15 at 15q21, the *CEP63* gene on chromosome 3 at 3q22, the *NIN* gene on chromosome 14 at 14q22, and the *CENPJ* gene on chromosome 13 at 13q12. The *ATR* gene is essential to the cell's DNA repair mechanism. It is not yet known how the other genes associated with Seckel syndrome contribute to the characteristic features of the disorder.
- **Silver-Russell syndrome:** The genetics of SRS are complex. Some cases result from loss of a process called methylation (the attachment of methyl groups to specific segments of DNA) to the *IGF2* and *H19* genes on chromosome 11. Loss of methylation disrupts the function of these genes, which direct normal cell and tissue growth. Other cases of SRS are caused by uniparental disomy (UPD), a condition in which the child inherits both copies of a chromosome from one parent and no copies from the other. In SRS, the child receives two copies of chromosome 7 from the mother alone, with no contribution from the father. It is possible

that other genes that have not been identified also play a role in the development of Silver-Russell syndrome.

In March 2015, an international team of scientists reported an association between the *XRCC4* gene on chromosome 5 at 5q14.2 and primordial dwarfism. This gene codes for a protein that is important in repairing double-strand breaks in DNA. Mutations in *XRCC4* are already known to be associated with increased susceptibility to breast cancer, lymphoma, bladder cancer, and multiple myeloma. It is thought that mutations in this gene may also lead to increased cell death, reduced cell growth and replacement, and the other growth failures associated with primordial dwarfism. The researchers did not, however, identify the *XRCC4* mutations with any of the specific subtypes of PD.

Demographics

Dwarfism by itself is not a particularly rare condition; estimates of the number of people in North America diagnosed with some form of dwarfism vary between 100,000 and 500,000. By contrast, primordial dwarfism is a rare occurrence. Silver-Russell syndrome is thought to occur in 1 in every 50,000 to 1 in every 100,000 live births; other subtypes of PD, for example MOPD type 2, are estimated to affect fewer than 100 persons worldwide, or less than 1 person in 3 million. Estimates of the number of persons with all subtypes of PD in Canada and the United States range between 100 and 1,000.

There is no indication that PD is more common in some racial or ethnic groups than in others, although further research may provide new evidence.

Signs and symptoms

While all subtypes of primordial dwarfism are marked by growth delays before and after birth, each of the subtypes has its own constellation of features.

MOPD type 1

Children with this type of PD typically have dry, aged-looking skin; thin, sparse hair on the scalp; and scanty eyebrows and eyelashes. In addition to microcephaly, their brains lack a corpus callosum, the band of nerve fibers that joins the two cerebral hemispheres. They also suffer from seizures and difficulty breathing. Some patients have defects in their hearing and vision, including glaucoma and proptosis (outward bulging of the eyes).

Skeletal abnormalities include hip displacement, abnormally short neck, bowing of the long bones in the legs, elongated collarbones, and reduced height of the spinal vertebrae.

KEY TERMS

Autosomal recessive—A pattern of inheritance in which two copies of a defective gene on a nonsex chromosome must be present for a disease or inherited trait to develop in an individual.

Autosome—Any human chromosome other than a sex chromosome.

Clinodactyly—A birth defect in which a finger (most often the little finger) is bent at an angle toward the neighboring finger (usually the fourth finger).

Craniosynostosis—A condition in which one or more of the fibrous joints in an infant's skull turns to bone prematurely. As the child's head continues to grow, the growth pattern of the skull is affected, resulting in a misshapen head and often deformed facial features.

Dwarfism—In general, a condition in which a person is unusually short in stature (adult height shorter than 4 ft. 10 in.) as the result of a genetic disorder, endocrine disorder, or skeletal abnormality. There are about 200 different conditions that can cause dwarfism.

Frontal bossing—The medical term for an unusually prominent forehead, often associated with an abnormally heavy brow ridge.

Intrauterine growth retardation (IUGR)—The slow or poor growth of a fetus during the mother's pregnancy. It can be caused by malnutrition or lack of an adequate oxygen supply to the fetus, as well as by genetic disorders.

Microcephaly—A neurological disorder in which the infant's or child's head is abnormally small. There is no universally accepted measurement for microcephaly, but it is commonly defined as a head circumference more than two standard deviations below the mean for the child's age and sex.

Microdontia—Abnormally small teeth.

Micrognathia—The medical term for an undersized or underdeveloped jaw.

Microtia—A birth defect in which the external ear is underdeveloped. The condition is called anotia if the outer ear is completely missing.

Osteodysplasia—A general term for a disorder of bone development.

Patella (plural, patellae)—The medical term for the kneecap.

Primordial—Referring to conditions that begin before birth or are characteristic of the embryo's earliest stages of development.

Proportionate dwarfism—Dwarfism in which the person's body parts are all smaller or shorter than normal but remain in proportion to one another.

Proptosis—Bulging of the eye outward from the orbit of the eye. It is also known as exophthalmos.

Uniparental disomy—A condition in which both members of a chromosome pair or segments of a chromosome are inherited from one parent without any contribution from the other parent.

MOPD type 2

Many patients with MOPD type 2 are born prematurely, either spontaneously or due to early induction of labor in response to fetal distress (indications that the fetus may not be well). Children with MOPD type 2 typically have more health problems than those with other forms of PD. These problems include abnormally small teeth (microdontia); unusually widely spaced teeth; a high-pitched, squeaky voice; sleep disorders in early life; frequent infections; farsightedness; feeding difficulties; and breathing difficulties. Some patients develop areas of abnormally light or dark skin pigmentation. Other patients have malformations in the blood vessels in the brain that lead to aneurysms (localized bulges in the wall of a blood vessel) and an increased risk of stroke. Girls with MOPD type 2 sometimes undergo precocious puberty, but this symptom has not been reported in boys with MOPD type 2.

Skeletal abnormalities include shortening of the forearms, premature closure of the epiphyses (the rounded ends of long bones), an abnormally narrow angle between the hip bone and the femur (the long bone in the thigh), scoliosis, loose ligaments, and dislocated joints. Another common feature is delayed bone age; that is, the maturation of the bones is slowed and may be as much as two to five years behind the child's chronological age.

Meier-Gorlin syndrome

Children with MGORS typically have curved collarbones and habitual dislocation of the elbow joints, as well as absent kneecaps and underdeveloped external ears. Bone age is usually delayed, and the epiphyses of the long bones are often flattened rather than rounded.

Meier-Gorlin syndrome can be distinguished from the other subtypes of PD by the fact that the child usually

attains a greater final height. Abnormalities in sexual development may occur in both boys and girls. Males may have undescended testicles (cryptorchidism), while females may have underdeveloped labia majora (external genital folds) and small breasts.

Seckel syndrome

In addition to a beak-like nose, other facial features characteristic of Seckel syndrome include abnormally large eyes, a narrow face, a receding forehead, misshapen ears, and micrognathia. Some patients have cleft palate, improper positioning of the teeth, erosion of the tooth enamel, or uneven development of the two sides of the face (facial asymmetry). Many children with Seckel syndrome develop disorders of the blood, including anemia (a low level of circulating red blood cells) and pancytopenia (a low level of circulating white blood cells, red blood cells, and platelets).

Skeletal abnormalities include craniosynostosis, malformation of the hip bones, scoliosis, dislocation of the forearm bones, clubfoot, and clinodactyly. In addition, some patients have only 11 pairs of ribs rather than the normal 12 pairs.

Silver-Russell syndrome

Children with SRS often have problems with low blood sugar (hypoglycemia) and increased sweating, along with delayed motor development resulting from lack of muscle mass and strength. In contrast to other subtypes of PD, children with SRS may appear to have relatively large heads compared to the small size of the rest of the body. About half of children with SRS have asymmetrical (uneven) growth.

Distinctive facial features include frontal bossing (broad and prominent forehead), a small chin, crowding of the teeth, and a thin upper lip. Other abnormalities include webbing between the toes (syndactyly) and a high-pitched voice. Males with SRS often have cryptorchidism and hypospadias (abnormal location of the urinary opening in the penis). Children with SRS are also at increased risk of certain forms of cancer, including Wilms' tumor and hepatocellular carcinoma.

Diagnosis

The diagnosis of primordial dwarfism can be made before birth by ultrasound imaging between 13 and 20 weeks gestation. Intrauterine growth retardation becomes evident at that point and becomes progressively worse over the course of the pregnancy. Molecular genetic testing can also be done before birth. The University of Chicago Genetic Services offers a comprehensive primordial dwarfism sequencing panel that includes sequence

QUESTIONS TO ASK YOUR DOCTOR

- Which subtype of primordial dwarfism does my child have?
- How long is my child likely to live?
- What are our chances of having another child with primordial dwarfism?
- Will my child have normal intelligence?
- What treatments and management will you recommend?

analysis of 16 different genes known to be associated with the five major subtypes of PD. The cost is \$4500. The department also offers sequence testing for individual genes.

In some cases, the diagnosis of primordial dwarfism is not made until after the infant is born. Such clinical signs as very low birth weight (as little as 3 lb.), short body length (less than 16 in.), facial deformities, and premature closure of the soft spots (fontanelles) in the skull indicate PD. The pediatrician may also order x-rays of the limbs to evaluate bone age; skeletal deformities like clinodactyly, dislocated joints, and scoliosis; and abnormalities of the skull and facial bones.

Some features of PD may not be fully apparent until the child is two or three years of age. One is delayed growth; for example, it can take a child with MOPD type 2 between two and five years to reach the body length of an average newborn. In addition, intellectual disability is easier to identify when the child is closer to school age.

Treatment and management

Treatment of children with primordial dwarfism varies according to the subtype of PD. As infants with MOPD type 1 rarely live beyond the first year of life, treatment is supportive only. Children with MOPD type 2 require careful monitoring that includes regular eye examinations for farsightedness, regular brain scans to detect aneurysms as early as possible, and yearly blood tests for blood sugar levels and other early signs of type 2 diabetes, beginning at age five.

Treatment of Meier-Gorlin syndrome and Seckel syndrome is highly individualized because the severity of specific symptoms varies from case to case. Surgery may be used to treat some dental and skeletal abnormalities. Most children with MGORS will require physical therapy; some will require special education. Children

with Seckel syndrome are rarely capable of attending school, as over 50% have an IQ below 50.

Silver-Russell syndrome is the one subtype of primordial dwarfism in which children may benefit from administration of growth hormone after age two. Recombinant human growth hormone is given on a daily basis by subcutaneous injection. The child typically requires physical therapy and special education in later childhood. Children with severe feeding difficulties may require surgical placement of a feeding tube.

Prognosis

The prognosis for children with primordial dwarfism is poor, as there was no cure for any of the subtypes. Life expectancy is limited, with patients with MOPD type 1 having the shortest expectancy. Patients with all types of PD, however, have reduced life expectancies, with only a few patients known to have lived past 30 years of age.

Rebecca J. Frey, PhD

Prion diseases

Prion(pronounced PREE-on) diseases are a class of degenerative central nervous system disorders. They are unique in that while some prion diseases have a genetic component, they may also be transmitted, and the infectious agent of the disease is a protein. Dr. Stanley Prusiner coined the term "prion," meaning "proteinaceous infectious particle," in 1982. His controversial, but finally accepted, research in the area of prion diseases led to his winning the Nobel Prize in Medicine in 1997.

Prion Diseases in Humans

There are five forms of prion disease known to occur in humans: kuru, Creutzfeldt-Jakob disease (CJD), Gerstmann-Sträussler-Scheinker disease (GSS), fatal familial insomnia (FFI), and new variant Creutzfeldt-Jakob disease, popularly known as "mad cow disease." Three of these, familial CJD, GSS, and FFI, are inherited disorders caused by mutations in a single gene on chromosome 20, while kuru and variant CJD are considered acquired prion diseases.

The prion diseases are also called transmissible spongiform encephalopathies (TSEs), because they can be transmitted between unrelated individuals and sometimes cause a sponge-like encephalopathy (degeneration of the brain tissue) in which vacuoles (holes) and other abnormal structures are formed in the brain. Prion diseases have also been identified in animals and include scrapie in sheep and goats, bovine spongiform encephalopathy (BSE) in cows, feline spongiform encephalopathy in cats, and chronic wasting disease in mules, deer, and elk.

Illustration of a prion protein. (Laguna Design/Science Photo Library/Alamy)

Prion diseases have all been associated with the function of a specific cellular protein called the prion protein (PrP). Like all cellular proteins, PrP is a long-chain molecule consisting of linked amino acids. A protein can assume many shapes: twisted into a spiral helix, extended into linear strands, or folded into sheets of aligned strands. Different shapes of the same molecular sequence are called isomers. It is theorized that the normal form of cellular PrP is a compact shape consisting mainly of four helix regions, whereas in the abnormal isomer (the prion), the protein is refolded into a sheet-helix combination. Furthermore, this prion triggers the conversion of normal PrP to the abnormal shape through an unknown mechanism. The abnormal isomer acts as a template to change more and more normal PrP to the abnormal structure. Therefore, once the protein exists in the abnormal form, it is an infectious agent that can be transmitted from one person to another.

Normal proteins are processed by proteases, which are enzymes present in the body that act to break down excess proteins in a process called proteolysis. However, the abnormal isomer of the prion protein is protease-resistant and cannot be broken down by the body's protease enzymes. Therefore, the abnormal prion protein continues to be produced without being processed. This condition leads to an accumulation of the abnormal protein in the body.

In several forms of prion disease, the abnormal prion protein aggregates in deposits, or plaques, in the brain tissue. It is believed that once the abnormal prion protein accumulates to a certain level in the body, the physical symptoms of impaired mental and physical functioning begin to show themselves. However, the exact mechanisms by which the abnormal isomer causes disease are not known. The onset of symptoms may not occur until the patient is age 60 or older, suggesting that either the rate of accumulation of the abnormal protein is initially slow or that some triggering event late in life causes the initial formation of the abnormal isomer, after which the disease can spread.

The normal function of the prion protein is not completely understood, but it is known to be involved with the functions of the synapses (nerve connections) in the brain. PrP is found in the highest concentrations in the brain. It is also found in the eyes, lungs, heart, kidney, pancreas, testes, and blood, and in the neuromuscular junction. The conversion of normal PrP to the infectious abnormal isomer form may disrupt the normal functions of the prion protein, and this process may be another cause of the degenerative symptoms of the disease.

Body tissues containing the abnormal isomer are a source of transmission of the disease between people

Color enhanced transmission electron micrograph of prions. These protein molecules are often found in direct connection with illnesses of the nervous system. The prions in this image were isolated from the brain of a hamster infected with scrapie-associated fibril. Other illnesses caused by prions include bovine spongiform encephalopathy (mad cow disease) in cattle, and Kuru and Creutzfeldt-Jakob disease in humans. (*Eye of Science/ Science Source*)

and even across species. Prion diseases are also found in animals, and in animal studies it has been shown that the disease can be spread through the ingestion of infected brain tissue. The transmission can also cross the species barrier; cows have become affected by prion disease after eating feed contaminated with infected sheep brain tissue. It is widely speculated that the outbreak of “mad cow” disease, the most publicized prion disease, was caused by infection from affected cows in the United Kingdom, although the mode of transmission has still not been determined. Transmission through oral ingestion was also shown to be the cause of kuru in the Fore tribe of New Guinea. After the Fore abandoned their practice of ritual cannibalism in which they consumed the brain tissue of ancestors, the incidence of kuru all but disappeared.

Other cases of human infection have been shown to be iatrogenic, or transmitted inadvertently during medical treatment. Most of these iatrogenic cases involve direct contact with brain and nervous system tissue. For example, CJD has been reported to result from the use of contaminated surgical instruments, corneal implants, implantation of dura mater or electrodes in the brain, and the injection of human growth hormones derived from cadaverous pituitary glands.

Other modes of transmission have been shown to be less efficient in animal studies. The recent outbreak of

new variant CJD caused increased concern about possible transmission through blood transfusions and plasma-derived products, but no case of new variant CJD has been proven to result from blood transfusion. Laboratory and epidemiological evidence supporting a strong risk of the spread of prion disease through blood transfusion have not been found, even though this area has been studied intensively.

Genetic profile

The gene that encodes the prion protein has been mapped to the short arm of chromosome 20 at 20p13. It has been named the *PRNP* gene. Mutations in the *PRNP* gene can cause alterations in the chemical sequence of amino acids in the prion protein, and this change is believed to make the protein more susceptible to assuming the abnormal conformation. Over 30 different mutations of the gene have been identified, encompassing point mutations (one base pair substituted for another in the gene sequence), insertions (additions to the gene sequence), and deletions (missing parts of the gene sequence). Depending on the specific mutation, different types of prion disease can appear in the patient.

It is estimated that 10% to 15% of prion disease cases are caused by inherited mutations of the *PRNP* gene. Because of the delayed onset of the disease and the wide variation in symptoms, more exact statistics are difficult to determine. The inheritance pattern is autosomal dominant, meaning that if either parent passes the mutated gene to their offspring, the child will be affected by the disease. A parent with prion disease has a 50% probability of passing on the mutated gene to his or her child.

Another genetic factor important in diagnosing prion disease is the genetic sequence of the *PRNP* gene. Like all genes, the *PRNP* gene is made up of two strands of DNA. Each DNA strand consists of a sequence of chemical structures called bases, and the two strands together form a sequence of base pairs. Three base pairs together form a unit called a codon, and each codon codes for a specific amino acid. At codon 129 of the *PRNP* gene, either the amino acid methionine (Met) or valine (Val) can be encoded. Because one copy of the *PRNP* gene is inherited from each parent, an individual may either be homozygous, having two of the same amino acids (Met-Met or Val-Val) at this position, or heterozygous, having different amino acids (Met-Val). Individuals who are homozygous appear to be more susceptible to infection of prion diseases, because it has been shown that a greater percentage of those infected are homozygous than in the general population.

In addition, the clinical symptoms (phenotype) of the prion disease can vary based on whether the individual is

Met-Met or Val-Val homozygous, and whether the individual has Met or Val on the same gene as another mutation. For example, a specific point mutation at codon 178 has been found to cause familial CJD if the individual has valine at codon 129 on the mutated gene, while the same mutation causes FFI when the individual has methionine at codon 129. In the case of GSS, the substitution of the amino acid leucine for proline at codon 102 has been found in most individuals diagnosed with GSS, and it is thought that this substitution is necessary for the development of GSS. In the case of FFI, the affected person must have asparagine at codon 178 instead of the usual aspartic acid.

Epidemiology

Prion diseases occur worldwide with a rate of one to two cases per one million. CJD is the most common of the prion diseases, while GSS and FFI are extremely rare, and kuru is now virtually non-existent due to the abandonment of the practice of cannibalism. There are 30 to 40 cases of familial CJD diagnosed each year in the United States. Males and females are equally susceptible to prion diseases. Several forms of prion disease usually do not cause identifiable symptoms until the individual is more than 60 years old, although other forms, such as FFI, have an earlier onset and are seen in teenagers and young adults.

Since prion disease can be either inherited or transmitted through infection, the demographics of the disease have both familial and environmental patterns. Inherited CJD is found with high frequency in Libyan Jews and also in other descendants of Sephardic Jews in Greece, Tunisia, Israel, Italy, Spain, and perhaps South America. Other genetic clusters have been identified in Slovakia, Poland, France, and Germany. Fatal familial insomnia has been linked to family pedigrees in Italy, Australia, the United States, and elsewhere. Families with GSS syndrome have been found in several countries in North America and Europe; the Indiana kindred, a family spanning eight generations, was the largest GSS family identified, with 57 members diagnosed with GSS.

The environmental clusters of acquired prion disease include the Fore, a remote tribe of New Guinea, in which kuru was transmitted through the practice of ritual cannibalism; a group of over 80 cases in Japan resulting from dura mater (brain membrane) grafts from a single surgical supply company; over 100 cases resulting from cadaveric human growth hormone injections in Europe and the United States; and, most famously, the 40-plus cases of new variant CJD or “mad cow” disease in the United Kingdom.

Signs and Symptoms

Prion disease primarily affects the brain and central nervous system, so its associated symptoms are all related to neurological function. These symptoms may include loss of muscular coordination and uncontrollable body movements (ataxia), visual problems, hallucinations, behavioral changes, difficulty in thinking clearly or remembering, sleep disturbances, speech impairment, and insanity. Such general complaints as headache, diminished appetite, and fatigue may occur prior to the onset of the more serious symptoms. The exact combination and severity of these symptoms vary widely among cases and types of prion disease.

Inherited Prion Diseases

FAMILIAL CREUTZFELDT-JAKOB DISEASE. CJD, named for the two German neuropathologists—Hans Gerhard Creutzfeldt (1885–1964) and Alfons Maria Jakob (1884–1931)—who first described it, is the most common of the inherited human prion diseases. It is characterized by a rapid deterioration in mental function from confusion and memory loss into severe dementia, accompanied by loss of muscular control (ataxia) and twitching or spasmodic motion (myoclonus). One distinctive feature of the dementia associated with the familial form of CJD is its startling speed of progression; family members will often say that they can see their loved one's mental abilities decline literally from one day to the next. Other symptoms include vision and speech impairment; patients with fCJD may go completely blind. A scan of electrical activity in the brain, called an electroencephalogram (EEG), will often show an abnormal periodic spike pattern. The onset of symptoms usually occurs when the patient is over age 50, and death follows within one to five years. Microscopic holes, called vacuoles, form within the brain tissue and give it a "spongiform" appearance characteristic of CJD.

GERSTMANN-STRÄUSSLER-SCHINKER DISEASE. Gerstmann-Sträussler-Scheinker disease (GSS) is named for the three Austrian neurologists who first described it in 1936: Josef Gerstmann (1887–1969), Ernst Sträussler (1872–1959), and Ilya Scheinker (1902–1954). The first mutation of the prion protein gene *PRNP* was identified in a GSS family in 1989.

GSS encompasses a variety of disorders. One form of the disease (the ataxic form) is first characterized by an unsteady walk, sometimes accompanied by leg pains. These motor problems get worse over several years and are finally accompanied by mental and behavioral breakdown. By contrast, dementia is the main characteristic of the telencephalic form of GSS, accompanied by rigidity, the inability to make facial expressions, tremors, and

stuttering or stammering. In another form of the disease, GSS with neurofibrillary tangles, the main features are loss of muscle coordination (ataxia), tremors, and progressive insanity. As in CJD, the affected individuals are usually in their 50s or older, and the progression of the disease may take from two to as long as 13 years. GSS is the most slowly progressing of the inherited prion diseases.

FATAL FAMILIAL INSOMNIA. FFI is the rarest of the inherited prion diseases. First reported in an Italian man in 1765, the disorder has been identified in fewer than 40 families worldwide. In the late 1990s, it was reported that there are about 25 families around the world who carry mutations for FFI: eight in Germany; five in Italy; four in the United States; two each in France, Australia, and England; and one each in Japan and Austria. In 2011, another family in the Netherlands was identified as carrying an FFI mutation.

The most noticeable sign of FFI is the untreatable and progressively worse difficulty in sleeping. The affected individual then begins to experience complex hallucinations that are often enacted dreams. Excessive sweating, irregular heartbeat, high blood pressure, and hyperventilation are other symptoms. Motor impairment may be present. Shortened attention span and memory loss has been observed. In the terminal stages, stupor and coma precede death. The average age at onset of symptoms is the mid-40s, and the disease progresses rapidly, with death resulting after about one year. Autopsy reveals the formation of dense tangles of neural fibers and astrocytes in the thalamus region of the brain. Genetic testing and counseling are considered essential for FFI, because the mutation that causes the disorder can now be identified by testing and because initial symptoms of the disorder do not appear until the person has reached childbearing age.

Acquired Prion Diseases

KURU. Kuru was called the "shivering disease" by the Fore tribe members, because its primary symptom was twitching and shaking of the body. This twitching began slowly and was not present when the person was completely still, but it then progressively worsened until any attempt at motion led to drastic and uncontrollable body movements, and the individual could no longer stand or walk. Mental insanity usually did not appear until the terminal stages of the disease. The onset of symptoms usually occurred in middle-aged individuals, and the course of the disease was short: three to 12 months.

VARIANT CREUTZFELDT-JAKOB DISEASE. The early signs of variant CJD (vCJD) are most often psychiatric

disturbances. Abnormal sensations of prickling or itching (paresthesia) or pain even from light touches (dysesthesia) are often present. So far, individuals affected with new variant CJD are much younger in age, typically teenagers and young adults. The duration of the disease is one to two years. As in familial CJD, vacuoles are present in the brain, but they are associated with dense deposits (plaques) of the abnormal PrP isomer.

The incidence of vCJD peaked in 2000, declining to about two cases per year since 2008. As of 2015, there had been about 177 cases of vCJD reported since 1996, with four cases reported in the United States.

Diagnosis

Because of the many different forms of prion disease and the overlap in symptoms with those of other, more common syndromes, prion diseases are often difficult to diagnose. Patients who are eventually identified with prion disease have been initially diagnosed with many other diseases, including Alzheimer's disease, Huntington's disease, Parkinson's disease, schizophrenia, multiple sclerosis, and myoclonic epilepsy. The number of possible diagnoses illustrates the difficulty in identifying the disease, and the importance of careful diagnosis to avoid unnecessary treatments.

A diagnosis of prion disease should be considered in any adult patient with signs of neurological impairment such as uncontrollable body movements, confusion, loss of memory, and cognitive degeneration, or psychiatric abnormality. Periodic discharges of brain waves, as observed on an EEG, are present in many, but not all, cases of prion disease. A magnetic resonance imaging (MRI) scan of the brain can rule out other causes of brain disease and potentially identify some abnormalities associated with prion disease. A biopsy, or sampling, of brain tissue can reveal the presence of abnormal PrP, although this procedure is generally not used in elderly patients because of the risk to the surgeon and other healthcare professionals.

Because the early symptoms of a prion disease are similar to those of such infectious disorders of the brain as neurosyphilis, encephalitis, or meningitis, doctors may begin the diagnostic process by taking a spinal tap in order to rule out infection as a cause of the patient's symptoms.

Genetic testing can reveal those cases of prion disease that are caused by mutations. The Centers for Disease Control and Prevention (CDC) has stated criteria for a diagnosis of fCJD as follows: a diagnosis of probable or possible fCJD in the patient, coupled with a diagnosis of possible or probable fCJD in a first-degree

QUESTIONS TO ASK YOUR DOCTOR

- What is a prion?
- How does a person "catch" a prion? Is the process similar to a viral or bacterial infection?
- How are prion infections treated?
- What is the direction of current research on prion diseases?

relative (parent, sibling, or child), plus detection of a mutation in the *PRNP* gene on molecular genetic testing.

Bismuth, mercury, or lithium poisoning result in symptoms quite similar to those of prion disease. These poisonings can be differentially diagnosed by blood tests.

The diagnosis of prion disease can be definitively confirmed by the transmission of the disease to an animal host such as a genetically engineered mouse. However, the transmission period may be quite long, as much as six to seven months. After death, prion disease can also be validated by autopsy of the brain tissue.

Treatment and management

At present, there is no known treatment that can prevent or reverse the transformation of the prion protein into its aberrant form. All treatments for prion disease are directed toward management of the symptoms. These treatments may include psychoactive drugs, electroconvulsive therapy (ECT), and professional care to ensure that the loss of physical and mental functions do not lead to accidental injury or death. Affected persons may wish to consider hospice care as the disease progresses toward complete incapacitation. Research into more advanced treatments is focusing on the application of gene therapies to block the formation of infectious PrP and drugs, which could act to stabilize the normal PrP structure. As with any inherited disease, genetic counseling is important in the management of the familial forms of prion disease.

Prognosis

Since the forms of prion diseases vary widely, the age at onset and rate of worsening of symptoms are also quite variable, but all prion diseases are incurable and fatal, with duration ranging from a few months to several years after onset. Some patients with GSS have been reported to live as long as 13 years after symptom onset, but this length of the disease course is exceptional.

Mechanism of Prion Misfolding and Downstream Effects

In 2021, scientists used sophisticated imaging techniques to visualize the location where misfolding of the prion protein begins. They then developed antibodies to the location of initial misfolding. With the help of the antibodies that bound to the location of initial misfolding, the misfolding stopped, and aggregation of prions stopped. This work has yielded insight into the pathology and a possible target for drug research.

Also in 2021, researchers announced that a protein implicated in other neurodegenerative diseases, TREM2, was at elevated levels in the blood and cerebrospinal fluid of prion disease patients. Working with laboratory models, scientists have determined that in some brain regions, TREM2 is transcribed from its gene at higher levels and that in some regions, the TREM2 message is translated at a higher rate than in controls. The function of TREM2 is unknown. This discovery may allow for diagnosis of a prion disease through a blood test, and it offers a potential target for drug development.

Propionic acidemia

Definition

Propionic acidemia is an inborn error of metabolism: a rare inherited disorder in which the body is unable to break down and use certain proteins properly. As a result, massive amounts of organic compounds (such as propionic acid, ketones, and fatty acids) build up in the blood and urine, interfering with normal body functions and development.

Description

Propionic acidemia, first described in 1961, usually shows up in the first few weeks after birth and, if untreated, results in mental and physical impairment. The disorder can have a broad range of clinical outcomes, ranging from the severe form that is fatal to newborns to the mild, late-onset form associated with periodic attacks of ketoacidosis, when organic compounds build up in the blood and urine. Other names for the disorder include ketotic hyperglycinemia, hyperglycinemia with ketoacidosis and lactic acidosis (propionic type), and propionyl CoA carboxylase (PCC) deficiency, types I and II.

Propionic acidemia can occur in isolation, or it can be a feature of multiple carboxylase deficiency, a condition involving abnormal production of many enzymes—all of which need biotin (a form of vitamin B)—as the result of an abnormality in biotin metabolism. Propionic acidemia is characterized by deficiency of an enzyme, propionyl CoA carboxylase, which the body requires to break down the amino acids isoleucine, valine, threonine,

and methionine (chemical building blocks of proteins). The deficiency can be caused by abnormal genes for making propionyl CoA carboxylase (isolated propionic acidemia) or by abnormal genes for metabolizing biotin (propionic acidemia resulting from multiple carboxylase deficiency).

Genetic profile

Propionic acidemia is an autosomal recessive disorder; that is, if a man and woman each carry one abnormal gene, then 25% of their children are expected to be born with the disorder. Two genes, *PCCA* and *PCCB*, code for the two parts (alpha and beta subunits) of the propionyl CoA carboxylase molecule.

The *PCCA* gene controls the production of alpha subunit and is on chromosome 13. Alterations in the *PCCA* gene result in type I propionic acidemia.

Researchers have identified 19 disease-causing mutations in the *PCCA* gene. Eight of these mutations result in an incomplete alpha subunit. Six mutations prevent the alpha subunit from binding biotin, which is required for propionyl CoA carboxylase to work properly, and results in multiple carboxylase deficiency. People who inherit two abnormal *PCCA* genes (homozygotes) produce only 1%–5% of the normal amount of propionyl CoA carboxylase. People who inherit one normal and one abnormal *PCCA* gene (heterozygotes) produce 50% of the normal amount of enzyme.

The *PCCB* gene, which controls the production of beta subunit, is on chromosome 3. Mutations in this gene are responsible for type II propionic acidemia.

Twenty-eight disease-causing mutations have been found in the *PCCB* gene. In people of Caucasian, Spanish, and Latin American heritage, researchers have found the most frequent mutation in about 32% of those with propionic acidemia. In people of Japanese heritage, two other mutations are most prevalent, occurring in 25% and 31% of Japanese patients. Homozygotes for the *PCCB* gene produce propionyl CoA carboxylase in amounts similar to homozygotes for the *PCCA* gene, but heterozygotes for the *PCCB* gene produce nearly normal amounts of propionyl CoA carboxylase. This is probably because many more beta subunits (four to five times more) are produced than alpha subunits, so even with decreased *PCCB* gene activity, enough beta subunits are available to combine with alpha subunits to make a complete molecule of propionyl CoA carboxylase.

Demographics

The frequency with which propionic acidemia occurs throughout the world is unknown because it is a rare

KEY TERMS

Amino acid—Organic compounds that form the building blocks of protein. There are 20 types of amino acids (eight are “essential amino acids” that the body cannot make and must therefore be obtained from food).

Biotin—A growth vitamin of the vitamin B complex found naturally in liver, egg yolks, and yeast.

Ketoacidosis—A condition that results when organic compounds (such as propionic acid, ketones, and fatty acids) build up in the blood and urine.

Multiple carboxylase deficiency—A type of propionic acidemia characterized by an inability to metabolize biotin.

Propionic acid—An organic compound that builds up in the body if the proper enzymes are not present.

Propionyl CoA carboxylase—An enzyme that breaks down the amino acids isoleucine, valine, threonine, and methionine.

disorder. However, in the United States, it affects roughly 1 in 100,000 people. Its occurrence does not appear to be specific to any particular population group. Considered to be prevalent among Inuits in Greenland, propionic acidemia has also been identified in other populations, including Austrian, Spanish, Latin American, Saudi Arabian, Amish, and Japanese people. Males and females are equally likely to be affected.

Signs and symptoms

Newborns with propionic acidemia are typically small and pale with poorly developed muscles. Symptoms that usually appear in the first weeks of life include poor feeding, vomiting, listlessness (lethargy), and ketoacidosis. Less often, infants with the disorder experience loss of body fluids (dehydration), seizures, and enlarged livers.

In some patients, the disorder appears later in life. Signs include facial abnormalities, such as puffy cheeks and an exaggerated “Cupid’s bow” upper lip. Patients with late-onset propionic acidemia may have acute inflammation of the brain (encephalopathy) or be developmentally delayed. These patients may have periodic attacks of ketoacidosis, usually brought on by eating too much protein, becoming constipated, or having frequent infections.

Patients with propionic acidemia as the result of having multiple carboxylase deficiency often have ketoacidosis and their urine may have a distinct “tom cat’s urine” odor. These patients may also have skin rash and loss of hair (alopecia).

Diagnosis

Physicians have only a few tests available that allow them to differentiate propionic acidemia from other inborn errors of metabolism. Tests that are absolutely specific for the disorder involve the measurement of propionyl CoA carboxylase and chemicals related to the reactions it affects. These tests are fairly uncommon and do not have published normal values.

Prenatal diagnosis of propionic acidemia is possible using cells obtained by amniocentesis. The cells can be tested for decreased activity of propionyl CoA carboxylase, for their ability to bind propionic acid, or for their methylcitrate levels.

In a newborn child, propionyl CoA carboxylase activity can be measured in white blood cells (leukocytes) from cord blood (blood from the umbilical cord). The infant’s blood and urine can be tested for increased levels of propionic acid. These levels are tested as well in older children and adults who are suspected of having the disorder.

Physicians can use genetic tests to analyze DNA and identify the specific gene, *PCCA* or *PCCA*, that is abnormal.

Treatment and management

The accepted treatment for propionic acidosis is a low-protein diet. Daily protein intake must be limited to 0.5–1.5 g/kg. Patients should eat frequent meals and avoid fasting, because fasting increases the body’s need for propionyl CoA carboxylate.

A low-protein diet keeps the number of ketoacidosis attacks to a minimum; however, such a diet does not prevent attacks. Physicians treat attacks of ketoacidosis by removing all protein from the patient’s diet and giving the patient sodium bicarbonate and glucose. If the attack is severe, proteins may be removed from the patient’s stomach by peritoneal dialysis.

Some patients may respond to a single oral dose (100 mg/kg) of L-carnitine, an organic compound. Others may be helped by antibiotics, which reduce the number of bacteria that produce propionic acid in the stomach. These are experimental treatments and have not been tested for long-term effects.

Patients with multiple carboxylase deficiency may receive biotin supplements (10 mg daily), which provide immediate, long-lasting improvement. Biotin supplements

QUESTIONS TO ASK YOUR DOCTOR

- What does the term “propionic acidemia” mean?
- What medical problems are associated with this disorder?
- One of my relatives was diagnosed with late-onset propionic acidemia. Is there a way to determine whether my children are at risk for this disorder?
- What information can a genetic counselor provide about this condition?

are not effective, however, for patients with other types of propionic acidemia.

Prognosis

The future of patients with propionic acidemia depends on the severity of the disorder. Left untreated, propionic acidemia in infants results in coma and death. With early diagnosis and treatment, some children are intellectually normal, while others’ lives may be complicated by intellectual disability and abnormal physical development. Some with propionic acidemia may be identified only during family studies. For patients with late-onset propionic acidemia, the disease can be controlled to some extent by diet, but many of these patients will also be mentally and physically delayed.

Prostate cancer

Definition

The prostate, a gland found only in men, is part of the reproductive system. Prostate cancer is a disease in which the cells of the prostate become abnormal and start to grow uncontrollably, forming tumors. Tumors that can spread to other parts of the body are called malignant tumors or cancers. Tumors that are not capable of spreading are called benign.

Description

The prostate is a gland that produces semen, the fluid that contains sperm. The prostate is about the size of a walnut and lies just beneath the urinary bladder. Usually prostate cancer is slow growing, but it can grow fast in some instances. As the prostate cancer grows, some of the cells break off and spread to other parts of the body through the lymphatic or the blood systems. This is called metastasis. The most common sites of spreading are the lymph nodes and various bones in the spine and pelvic region.

The cause of prostate cancer is not clear; however, several risk factors are known. The average age at diagnosis of prostate cancer is around 72. In fact, 80% of prostate cancer cases occur in men over the age of 65.

As men grow older, the likelihood of their getting prostate cancer increases. Hence, age is one of the more important risk factors for prostate cancer. Race may be another contributing factor. African Americans have the highest rate of prostate cancer in the world, while the rate in Asians is one of the lowest. Although the rate of prostate cancer in native Japanese is low, the rate in Japanese Americans is closer to that of white American men. This pattern suggests that environmental factors also play a role in prostate cancer.

There is some evidence to suggest that a diet high in fat increases the risk of prostate cancer. Studies also suggest that nutrients such as soy isoflavones, vitamin E, selenium, vitamin D, and carotenoids (including lycopene, the red color agent in tomatoes and beets) may decrease prostate cancer risk. Vasectomy may be linked to increased prostate cancer rates. Similarly, workers in industries, such as welding, with exposure to the metal cadmium appear to have a higher than average risk of prostate cancer. Male sex hormone levels may also be linked to the rate of prostate cancer. In addition, some studies have linked increased prostate cancer risk to smoking.

Genetic profile

An estimated 5%–10% of prostate cancer is due to a hereditary cause. Among men with early prostate cancer, a hereditary cause is likely in up to one-third of cases before age 60, and almost half of men diagnosed at age 55 or younger. Studies have found around a two-to-three-fold increased rate of prostate cancer in close relatives of men with the disease. Hereditary prostate cancer is likely in a family if there are three cases of prostate cancer in close relatives or three affected generations on either the mother's or father's side or two relatives with prostate cancer before age 55.

Prostate cancer: pedigree analysis chart (Gale)

Studies suggest that hereditary prostate cancer is likely to be caused by several different genes instead of a single gene. The, *HPC1* (hereditary prostate cancer gene 1), located on the first chromosome pair at 1q24-25, was the first gene found to cause hereditary prostate cancer. At least four other genes have been reported, including one thought to increase the risk of both prostate and brain tumors. Other genes known to increase the risk of other cancers, such as breast cancer, are also linked to prostate cancer. These genes include *BRCA1*, *BRCA2*, and *HOXB13*. When a mutation in one or more of these genes is inherited, it is inherited in an autosomal dominant pattern. *BRCA1* and *BRCA2* are genes that code for tumor suppressor proteins. When these genes are not coded correctly, the proteins are unable to suppress the overgrowth of cells, thus leading to tumors and cancer. The *HOXB13* gene is responsible for coding proteins that regulate activities of other genes, also likely a tumor suppressor. Other tumor suppressor genes associated by studies to prostate cancer are *CAVI*, the *CDKIs*, *CCNA1*, *CCNA2*, *DAPK*, *FHIT*, *HIC1*, *LPL*, and others. Common variations in certain genes also may increase susceptibility to prostate cancer, including genes linked to androgen, a sex hormone, and *PSA* and *TMPRSS2-ETS*. Since no clear cause has been identified for the majority of hereditary prostate cancer, genetic testing is typically done through research studies. Ongoing research seeks to determine the relationship among the approximately 40 genes that may have a role in prostate cancer.

Demographics

Prostate cancer is the most common cancer among men in the United States and is the second leading cause of cancer deaths. One in seven men in the United States

will be diagnosed with prostate cancer at some point in their lives, most after the age of 65. Prostate cancer affects African American men about twice as often as it does Caucasian men, and the mortality rate among African Americans is also higher. African Americans have the highest rate of prostate cancer in the world. The prostate cancer rate varies considerably around the world. The highest rates are in North America and Western Europe; by contrast, the rates are moderate in Africa and lowest in Asia. It is unclear what roles genetics, diet, economics, and healthcare access play in these rates.

Signs and symptoms

Frequently, prostate cancer has no symptoms, and the disease is diagnosed when the patient goes for a routine screening examination. However, occasionally, when the tumor is larger or the cancer has spread to the nearby tissues, the following symptoms may occur:

- weak or interrupted urine flow
- frequent urination (especially at night)
- difficulty starting urination
- inability to urinate
- pain or burning sensation when urinating
- blood in the urine
- persistent pain in lower back, hips, or thighs (bone pain)
- difficulty having or keeping an erection (impotence)

Diagnosis

Although prostate cancer may be slow-growing, it can be quite aggressive, especially in men under the age of 40. When the disease is slow-growing, it may go undetected. Because it may take many years for the cancer to develop, men with the disease are likely to die of other causes rather than from the cancer.

Prostate cancer is frequently curable when detected early. However, because the early stages of prostate cancer may not have symptoms, it often remains undetected until the patient goes for a routine physical examination. Diagnosis of the disease is made using some or all of the following tests.

Digital rectal examination (DRE)

In order to perform this test, the doctor puts a gloved, lubricated finger (digit) into the rectum to feel for any lumps in the prostate. The rectum lies just behind the prostate gland, and a majority of prostate tumors begin in the posterior region of the prostate. If the doctor does detect an abnormality, he or she may order more tests in order to confirm these findings.

Cancer biomarkers

Cancer biomarkers are molecules in the body that can be tested to predict outcome, confirm diagnosis, and provide treatment recommendations. Depending on the biomarker, they can be detected in the blood, urine, or from a biopsy of the prostate. One of the most commonly tested biomarkers is prostate-specific antigen (PSA), which can be measured in the blood. The cells lining the prostate generally make this protein, and a small amount can be detected in the bloodstream. Prostate cancers typically produce a lot of this protein, and it can be easily detected in the blood. Hence, when PSA is found in the blood in higher than normal amounts, cancer may be present. PSA can also be used in monitoring treatment. Although PSA tests can be useful, sometimes they indicate that individual has prostate cancer when he does not, and sometimes they miss a diagnosis. PSA testing cannot tell how serious the prostate cancer is.

Urine biomarkers look at changes in genes and proteins that are specific to prostate cancer that are shed from the prostate. These types of biomarkers help to determine if a biopsy is necessary. Other biomarkers are DNA, mRNA, and protein types and levels found in tumor tissue that are associated with prostate cancer. These typically help monitor tumor aggressiveness, how well treatment is working, and whether a negative biopsy is correct.

Transrectal ultrasound

A small probe is placed in the rectum and sound waves are released from the probe. These sound waves

bounce off the prostate tissue, and an image is created. Since normal prostate tissue and prostate tumors reflect the sound waves differently, the test can be used to detect tumors. Though the insertion of the probe into the rectum may be slightly uncomfortable, the procedure is generally painless and takes only about 20 minutes.

Prostate biopsy

If cancer is suspected from the results of any of the above tests, the doctor will remove a small piece of prostate tissue with a hollow needle. This sample is then checked under a microscope for the presence of cancerous cells. Prostate biopsy is the most definitive diagnostic tool for prostate cancer.

If cancer is detected during the microscopic examination of the prostate tissue, the pathologist will “grade” the tumor. This means that the tumor will be scored on a scale of 2–10 to indicate how aggressive the tumor is. Tumors with a lower score are less likely to grow and spread than are tumors with higher scores. This method of grading tumors is called the Gleason system. This is different from “staging” of the cancer. When a doctor stages a cancer, the doctor gives it a number that indicates whether it has spread and the extent of spread of the disease. In Stage I, the cancer is localized in the prostate in one area, whereas in the last stage, Stage IV, the cancer cells have spread to other parts of the body.

On the left, a normal prostate. On the right, a prostate with cancer. A tumor may constrict urine flow from the bladder. (Monica Schroeder/Science Source)

KEY TERMS

Anti-androgen drugs—Drugs that block the activity of the male hormone.

Benign—A noncancerous tumor that does not spread and is not life-threatening.

Benign prostatic hyperplasia (BPH)—A noncancerous condition of the prostate that causes growth of the prostate tissue, thus enlarging the prostate and blocking urination.

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes.

Cancer biomarkers—A molecule found in the body like a protein or gene that can suggest prognosis and what type of therapies would be best. In some cases they can even predict the risk of cancer in people who do not have cancer.

Chemotherapy—Treatment of cancer with synthetic drugs that destroy the tumor either by inhibiting the growth of the cancerous cells or by killing the cancer cells.

Estrogen—A female sex hormone.

Hormone therapy—Treatment of cancer by changing the hormonal environment, such as testosterone and estrogen.

Lymph node—A bean-sized mass of tissue that is part of the immune system and is found in different areas of the body.

Malignant—Describes a tumor growth that spreads to another part of the body, usually cancerous.

Metastasis—The spreading of cancer from the original site to other locations in the body.

Prostatectomy—The surgical removal of the prostate gland.

Radiation therapy—Treatment using high-energy radiation from x-ray machines, cobalt, radium, or other sources.

Rectum—The end portion of the intestine that leads to the anus.

Semen—A whitish, opaque fluid released at ejaculation that contains sperm.

Seminal vesicles—The pouches above the prostate that store semen.

Testicles—Two egg-shaped glands that produce sperm and sex hormones.

Testosterone—Hormone produced in the testicles that is involved in male secondary sex characteristics.

Transrectal ultrasound—A procedure in which a probe is placed in the rectum. High-frequency sound waves that cannot be heard by humans are sent out from the probe and reflected by the prostate. These sound waves produce a pattern of echoes that are then used by the computer to create sonograms or pictures of areas inside the body.

X-rays and imaging techniques

X-ray studies may be ordered to determine whether the cancer has spread to other areas. Imaging techniques (such as computed tomography scans and magnetic resonance imaging), for which a computer is used to generate a detailed picture of the prostate and areas nearby, may be done to get a clearer view of the internal organs. A bone scan may be used to check whether the cancer has spread to the bone.

The American Cancer Society and other organizations recommend that PSA blood testing and DRE be offered to men with at least a ten-year life expectancy beginning at age 50. Men at higher risk for prostate cancer, such as those with a family history of the disease or African American men, may wish to consider screening at an earlier age such as 45. A low-fat diet may slow the progression of prostate cancer. Hence, the American Cancer Society recommends a diet rich in fruits, vegetables, and dietary fiber, and low in red meat and saturated fats, in order to reduce the risk of prostate cancer.

Treatment and management

The doctor and the patient decide on the treatment after considering many factors. For example, the patient's age, the stage of the tumor, the patient's general health, and the presence of any coexisting illnesses have to be considered. In addition, the patient's personal preferences and the risks and benefits of each treatment method are also taken into account before a decision is made. Molecular genetic analysis using biomarkers is a recent approach to treatment and management of prostate cancer. Biomarkers that indicate gene variants can provide information on what genes to target in terms of pharmaceuticals.

Surgery

For early-stage prostate cancer, surgery is frequently considered. Radical prostatectomy involves complete removal of the prostate. During the surgery, a sample of the lymph nodes near the prostate is removed to determine whether the cancer has spread beyond the prostate gland.

Because the seminal vesicles (the gland where sperm is made) are removed along with the prostate, infertility is a side effect of this type of surgery. In order to minimize the risk of impotence (inability to have an erection) and incontinence (inability to control urine flow), a procedure known as “nerve-sparing” prostatectomy is used.

In a different surgical method, known as the transurethral resection procedure (TURP), only the cancerous portion of the prostate is removed, by using a small wire loop that is introduced into the prostate through the urethra. This technique is most often used in men who cannot have a radical prostatectomy due to age or other illness, and it is rarely recommended.

Radiation therapy

Radiation therapy involves the use of high-energy x-rays to kill cancer cells or to shrink tumors. It can be used instead of surgery for early-stage cancer. The radiation can either be administered from a machine outside the body (external beam radiation), or small radioactive pellets can be implanted in the prostate gland in the area surrounding the tumor.

Hormone therapy

Hormone therapy is commonly used when the cancer is in an advanced stage and has spread to other parts of the body. Prostate cells need the male hormone testosterone to grow. Decreasing the levels of this hormone, or inhibiting its activity, may cause the cancer to shrink or stop growing. Hormone levels can be decreased in several ways. Orchiectomy is a surgical procedure that involves complete removal of the testicles, leading to a decrease in the levels of testosterone. Alternatively, drugs (such as *LHRH* agonists or anti-androgens) that bind to the male hormone testosterone and block its activity can be given. Another method tricks the body by administering the female hormone estrogen. When this is given, the body senses the presence of a sex hormone and stops making the male hormone testosterone. However, there are some side effects to hormone therapy. Men may have hot flashes, enlargement and tenderness of the breasts, or impotence and loss of sexual desire, as well as blood clots, heart attacks, and strokes, depending on the dose of estrogen.

Chemotherapy

Chemotherapy is the use of drugs to kill cancer cells. The drugs can either be taken as a pill or injected into the body through a needle that is inserted into a blood vessel. This type of treatment is called systemic because the drug enters the blood stream, travels through the whole body, and kills the cancer cells that are outside the prostate. Chemotherapy is sometimes used to treat prostate cancer

QUESTIONS TO ASK YOUR DOCTOR

- Why is prostate cancer designated as a genetic disorder?
- Are genetic tests available to determine whether a person is at risk for prostate cancer?
- What kind of tests should a man have to determine if he has early-stage prostate cancer, and at what age should he have those tests?
- What is the prognosis for a man diagnosed with prostate cancer, and what factors affect this prognosis?

that has recurred after other treatment. Research is ongoing to find more drugs that are effective for the treatment of prostate cancer.

Immunotherapies

Immunotherapy uses the person’s own immune system to kill cancer cells. Immunotherapies include vaccines that target cancer cells. Other immunotherapies use antibodies that attack the cancer cells. Although immunotherapy is promising, it is still in the early stages of research and development and is not widely used.

Focal ablation of prostate cancer

Focal ablation of prostate cancer destroys a targeted region of cancer using extreme cold, high-intensity ultrasound, light therapy with a light sensitive drug, lasers, or magnets. This type of therapy is still in the early stages of development. It shows promise as it can have fewer side effects than other treatments.

PARP Inhibitors

PARP inhibitors are medications that block PARP, an enzyme found in the body that can help cancer cells grow by repairing their DNA. By blocking PARP, these medications can result in targeted death of the cancer cells. These medications are typically used for men who are not responsive to traditional treatments with specific gene variations in the BRCA gene.

Watchful waiting

Watchful waiting means no immediate treatment is recommended, but doctors keep the patient under careful observation. This option is generally used in older patients when the tumor is not aggressive and the patients have other, more life-threatening illnesses. Prostate cancer in

older men tends to be slow-growing. Therefore, the risk of the patient dying from prostate cancer, rather than from other causes, is relatively small.

Prognosis

According to the American Cancer Society, the survival rate for all stages of prostate cancer combined has increased from 50% to 87% between 1990 and 2020. Due to early detection and better screening methods, nearly 60% of the tumors are diagnosed while they are still confined to the prostate gland. The five-year survival rate for early-stage cancers is almost 99%. Sixty-three percent of the patients survive ten years, and 51% survive 15 years after initial diagnosis. Studies on the prognosis of hereditary prostate cancer are ongoing. One study found that the mortality for African Americans with prostate cancer, after surgery for removal of the prostate, is 20% higher relative to Caucasians of similar education, income, and health insurance. Asian Americans and Pacific Islanders, by contrast, had a 35% lower mortality than Caucasians.

Protein C deficiency

Definition

Protein C deficiency is a lack of sufficient functioning protein C in the blood. Protein C is a substance that helps to prevent blood clots. Persons with this disorder may have no symptoms, mild symptoms, or severe and even life-threatening symptoms.

Description

Protein C deficiency was discovered in 1981, just six years after protein C was first isolated. In a 1981 paper published in the *Journal of Clinical Investigations*, researchers described a connection between low concentrations of protein C in the blood plasma (the liquid portion of the blood) and blood clotting. It is now known that protein C plays a crucial role in the series of steps involved in blood clotting. One of protein C's roles in this pathway is to regulate the blood-coagulation protein thrombin. With too little properly functioning protein C to control thrombin's activity, multiple clots can form.

Low levels of protein C may have explicit effects, and in some individuals, these include dark, reddish-purple blotches, which sometimes extend over considerable areas of the body. Such blotching is known as purpura fulminans. Newborns with severe protein deficiency may display considerable blotching, as well as painful black sores, particularly on the back of the head and the buttocks. This is a life-threatening condition.

KEY TERMS

Deep vein thrombosis—A blood clot in a deep vein, usually in the legs.

Eschars—Painful patches of dead, blackened tissue.

Mesentery—Double-layered fold in the peritoneum.

Parenchyma—Functional (rather than structural) tissues of an organ.

Pulmonary embolism—A blood clot in the lungs.

Purpura fulminans—Dark, reddish-purple patches of dying tissue that result from clots in small blood vessels that would otherwise feed that tissue.

Venous thromboembolism—A blood clot that breaks free of its location in a vein and moves elsewhere in the body.

While in the past many young patients died from the effects of severe protein C deficiency, medical advancements coupled with a better understanding of protein C have led to intensive treatment and monitoring options that allow many patients to survive and thrive.

Genetic profile

Protein C deficiency often results from an abnormal *protein C* gene, which is located on chromosome 2. Hereditary protein C deficiency is inherited in an autosomal dominant manner, which means that an individual need only inherit the abnormal gene from one parent. This circumstance often occurs when one parent is heterozygous for the trait or has one normal copy of the gene and one abnormal copy of the gene. When such is the case, that parent's children have a 50% chance of inheriting the abnormal gene. If both parents are heterozygous for the trait, a child's chance of inheriting the abnormal gene jumps to 75%, but the child also has a 25% chance of inheriting two copies of the abnormal gene—one from each parent. A child with two copies of the abnormal gene is said to have homozygous protein C deficiency.

Demographics

Many people have some level of protein C deficiency, although they have no symptoms. It is estimated that 1 in 200–500 individuals has such a deficiency. Significant protein C deficiency is much rarer, occurring in just 1 person of every 20,000. The most severe form of the disorder, homozygous protein C deficiency, occurs

when an individual inherits an abnormal *protein C* gene from each parent. Homozygous protein C deficiency is exceptionally rare. Estimates for the incidence of homozygous protein C deficiency range from 1 in 500,000 to less than one per million.

Signs and symptoms

Protein C deficiency comes in two types:

- Type I protein C deficiency occurs when an individual has perfectly functioning protein C but has too little of it. Kidney disease or a number of other diseases can prompt an individual's body to produce too little protein C. Type I may also result when individuals have inherited one abnormal *protein C* gene from one of their parents. Regardless of its cause, people who have too low a level of protein C cannot control thrombin, and this situation causes blood clots to form.
- Type II protein C deficiency occurs when individuals are able to make sufficient protein C, but the protein C that is made does not function correctly and cannot play its proper role in the coagulation cascade. Genetic mutations can cause the production of nonfunctioning protein C.

Scientists have found that protein C not only interacts with thrombin, but also with other molecules involved in blood clotting, and they have identified more than 270 mutations that can occur in the *protein C* gene.

Symptoms

The symptoms of homozygous protein C deficiency and severe heterozygous protein C deficiency are typically evident very soon after birth. They include:

- Appearance and rapid progression of purpura fulminans, which often begin as large red to purple lesions, often at the back of the head or on the buttocks. Purpura fulminans result from clots in small blood vessels that would otherwise feed that tissue. They typically develop quickly into black scabs of dead tissue known as eschars, which are extremely painful.
- Blindness due to blood clots in the veins of the retina.
- Blood clots in large blood vessels, including those of the kidneys.

As patients with severe protein C deficiency age, they typically have recurring problems with purpura fulminans, particularly following injuries, infections, or changes in anticoagulating therapeutic regimens.

Individuals with moderately severe protein C deficiency may not have their first symptoms until they reach their teens or older. These symptoms may include:

- Recurring venous thromboembolism, which is a blood clot that breaks free of its location in a vein and moves elsewhere in the body, sometimes into the lungs (a pulmonary embolism).
- Deep vein thrombosis, or a blood clot in a deep vein, usually in the legs.
- Clots in organ tissues (parenchyma).
- Blood-clotting proteins that become overly active and disseminated (intravascular coagulation).

In the mild form of protein C deficiency, the patient's body makes functional protein C but makes it in insufficient amounts. Some people who have this condition may experience no problems at all. Others may have one or more of the following symptoms:

- recurring blood clots that may affect blood flow and may lead to a pulmonary embolism
- deep vein thrombosis
- arterial ischemic stroke, due to a blood clot in an artery that feeds the brain
- clots in the mesentery, a double-layered fold in the peritoneum of the abdomen
- blood clots that occur during pregnancy

Diagnosis

Examination

Doctors will suspect protein C deficiency in infants born with obvious purpura fulminans, particularly those who quickly develop eschars. They may also suspect this disorder in older patients who develop the reddish-purple patches or who experience recurring blood clots.

Tests

Doctors will order blood tests to measure the amount of functional protein C and/or to measure the total amount of protein C—functional or not—in the bloodstream. The doctor may repeat the test to make sure that the measured rate is not fluctuating. Another test that a doctor may order involves making tiny nicks in the arm to measure how long the patient continues to bleed and to learn about the clotting activity in the patient.

Treatment and management

Individuals who have protein C deficiency can take various measures to reduce the occurrence of blood clots. These include making typical healthy-lifestyle choices such as eating a balanced diet, remaining physically active, maintaining a healthy weight, and refraining from tobacco use. Avoiding prolonged immobility, such as sitting still on long car rides or plane trips, can

QUESTIONS TO ASK YOUR DOCTOR

- I have mild protein C deficiency and would like to have a baby. Am I at risk for developing venous thrombosis and, if so, what precautions can I take? Are there other risks I should know about?
- My child has just been diagnosed with protein C deficiency, but my other children seem fine. At what age should they be tested for this disorder?
- I understand that several tests are available to test for protein C deficiency. Which do you recommend and why?
- I have protein C deficiency and am going to undergo surgery that will keep me off my feet for more than a week. What special care should I expect at the hospital, and what precautions can I follow once I return home to avoid blood clots while I am recovering?

also be helpful. Persons who are (or expect to be) bedridden due to surgery or illness should discuss with their doctor options for reducing their risk of blood clots. The treatment for patients with protein C deficiency varies based on the severity of the disorder and the individual's symptoms.

Traditional

The doctor may order the administration of protein C, usually as fresh frozen plasma or as protein C concentrate. This is a typical treatment for patients with infantile protein C deficiency.

Drugs

Some patients may receive anticoagulants, such as a form of heparin or warfarin, to counter current clots and, in some cases, to help prevent future clots.

Prognosis

Individuals who have homozygous protein C deficiency often experience fatal thrombosis unless they receive replacement protein C through fresh frozen plasma or through protein C concentrate. Patients who have milder forms of the disorder and have associated symptoms typically have a good outcome with treatment, although they may experience symptoms now and again. Many people who have protein C deficiency never have any symptoms and lead normal lives.

Protein S deficiency

Definition

Protein S deficiency is a disorder caused by an insufficient amount of functioning protein S in the blood. Protein S is a substance that helps to prevent blood clots. Normally, the body has a balance between components that promote clotting and those that prevent it, so that clots form only under certain conditions. In individuals with protein S deficiency, too many clots occur. Some people are born with this deficiency, whereas others develop it because of liver disease or due to a lack of vitamin K. Some people with protein S deficiency never have symptoms, but others experience blood clots, embolisms, miscarriages, and, in a few cases, death.

Description

Protein S is a relatively new discovery. Researchers first identified it in the late 1970s. This protein is vitamin K-dependent, which means that vitamin K is necessary for its production. Protein S plays an important role in the steps necessary to control coagulation in the human body, and without it, blood clotting becomes abnormal. In particular, protein S is involved in the action of various

KEY TERMS

Deep vein thrombosis—A blood clot in a deep vein, usually in the legs.

Pulmonary embolism—A blood clot in the lungs.

Purpura fulminans—Dark, reddish-purple patches of dying tissue that result from clots in small blood vessels that would otherwise feed that tissue.

Thrombophlebitis—Inflammation of veins due to blood clots.

Vitamin K—A vital substance that is obtained by eating certain foods, such as leafy greens, but mainly through bacterial manufacture in the large intestine.

blood-clotting substances (such as protein C, factor V, and factor VIII). When the levels of protein S are too low, blood clots can occur. People can obtain vitamin K by eating certain foods, such as leafy greens, but they mainly get their vitamin K from bacteria in the large intestine. These bacteria actually make vitamin K, and they usually make plenty to provide all the vitamin K that a person needs.

The main health problem associated with protein S deficiency is blood clotting, or thrombosis. Protein S is important in the blood-clotting pathway because it is one of a number of anticoagulation proteins that keep the blood from clotting abnormally. In particular, protein S joins with another anticoagulant, protein C, to shut down the clotting action of the enzyme thrombin. Without enough functioning protein S, protein C alone cannot stop thrombin's clotting activity, and it is left to produce clots when it should not. These clots can lodge in blood vessels, where they can limit or stop blood flow. This hindrance of blood flow can be dangerous, and even lethal. Fortunately, various treatments exist to treat abnormal blood clotting.

Genetic profile

Protein S deficiency can result from liver disease or insufficient vitamin K, but it is often a congenital condition resulting from at least one mutated protein S gene that is inherited from a parent.

Hereditary protein S deficiency results from mutations in the protein S gene *PROS1*. *PROS1* is located on chromosome 3. Two of the known mutations of this gene—and several others probably exist—include deletions of parts of the gene such that the mutated gene's

instructions for making the protein are no longer complete. A short, improperly functioning protein results.

Hereditary protein S deficiency is inherited in an autosomal dominant manner, which means that an individual need inherit the abnormal gene from only one parent. This situation often occurs when one parent is heterozygous for the trait or has one normal copy of the gene and one abnormal copy of the gene. When such is the case, that parent's children have a 50% chance of inheriting the abnormal gene. If both parents are heterozygous for the trait, the child's chance of inheriting the abnormal gene not only jumps to 75%, but the child also has a 25% chance of inheriting two copies of the abnormal gene—one from each parent. A child with two copies of the abnormal gene is said to have homozygous protein S deficiency.

Demographics

Protein S deficiency occurs in about 1 of every 20,000 individuals. Some individuals may have no symptoms and, therefore, be unaware they have the condition. In others, first symptoms may not appear until adulthood, but they usually materialize before middle age. A much rarer form of the protein S deficiency is the hereditary form of the disorder, known as homozygous protein S deficiency. Homozygous protein S deficiency generally makes its presence known in newborns or infants as purpura fulminans, which is the formation of purplish patches of dying tissue on the body that can sometimes be quite large. These patches are caused by blood clots in small blood vessels that would otherwise feed that tissue.

Signs and symptoms

Symptoms

Many individuals with protein S deficiency never experience any symptoms, and some only become aware that they have it when they undergo testing because a close relative develops the disorder. Among those who do experience problems associated with the disorder, symptoms can range from mild to severe. Symptoms may include the following:

- purpura fulminans, mainly in individuals with homozygous protein S deficiency
- recurring blood clots that may affect blood flow and may move into the lungs (pulmonary embolism)
- blood clot in a deep vein, usually in the legs (deep vein thrombosis)
- inflammation of veins due to blood clots (thrombophlebitis)
- miscarriage
- swelling and pain in the legs due to venous thrombosis

QUESTIONS TO ASK YOUR DOCTOR

- I have protein S deficiency, and the doctor has prescribed heparin. Am I still at any risk of having a dangerous blood clot?
- Will I have to take anticoagulants for the rest of my life?
- What are the signs of blood clots, and should I consult a doctor if I find any of these signs?
- What is the chance that I will pass my own protein S deficiency to any children I may have in the future? Is it prudent for me to pursue a pregnancy?
- Would it be beneficial to eat a diet high in food rich in vitamin K?

Diagnosis

Examination

Doctors may want to test a patient for protein S deficiency when they learn of a family history of the disorder, particularly when it is combined with the presence of one or more of the following symptoms:

- deep vein thrombosis
- thrombophlebitis
- purpura fulminans
- swelling and pain in the legs, possibly accompanied by redness
- recurring blood clots, particularly in individuals of middle age or younger
- cord-like, hard veins, which are indicative of clotting

Tests

Doctors will order blood tests to measure the amount of functional protein S and/or to measure the total amount of protein S—functional or not—in the bloodstream. Doctors may repeat the test to make sure that the measured rate is not fluctuating. Another test that may be ordered involves making small nicks in the arm to measure how long the patient continues to bleed and, therefore, to provide information about the patient's clotting activity.

Treatment and management

Individuals who have protein S deficiency can take various measures to reduce the occurrence of blood clots. These include making typical healthy-lifestyle choices such as eating a balanced diet, remaining physically

active, maintaining a healthy weight, and refraining from tobacco use. Avoiding prolonged immobility, such as sitting still on long car rides or plane trips, can also be helpful. Persons who are (or who expect to be) bedridden due to surgery or illness should discuss with a doctor options for reducing the risk of blood clots. Women who are considering a pregnancy or beginning birth control or certain types of hormone-replacement therapies should consult a doctor first.

The treatment for protein S deficiency varies based on the patient's symptoms. Symptoms are wide-ranging because numerous protein S mutations can occur, and these can have different effects.

Traditional

For patients diagnosed with protein S deficiency, doctors typically recommend that the person follow a healthy lifestyle in terms of diet and exercise to lower the risk of blood clots. To treat an already existing clot, a doctor may recommend that the patient receive fresh frozen human plasma, which contains protein S.

Drugs

Some patients may receive anticoagulants, such as a form of heparin or warfarin, to counter current clots and, in some cases, to help prevent future clots. The use of such drugs is particularly common for women who are pregnant, because even in a person without this disorder, the level of protein S dips during pregnancy. In addition, women who take some forms of birth control pills or certain types of hormone-replacement therapies may experience additional drops in protein S.

Prognosis

Some individuals with mild forms of this disorder never experience any symptoms and have no problems associated with the condition. Others may have symptoms ranging from mild to severe. Many people with protein S deficiency have a good outcome, particularly when they follow the advice of a physician. Even with the use of anticoagulants, however, life-threatening blood clots do occur occasionally, and some patients die from them.

Proteus syndrome

Definition

Proteus syndrome is characterized by excessive growth of cells. This can result in asymmetrical growth, benign (noncancerous) tumors, and pigmented skin lesions.

Description

Proteus syndrome is a rare condition that was first described by Michael Cohen in 1979. Hans-Rudolf Wiedemann named the condition after the Greek god Proteus who could assume many forms. The disorder gained wide recognition when it became publicized that Joseph (John) Merrick, the person depicted in the movie *The Elephant Man*, was suspected of having Proteus syndrome.

The excess growth of tissue that characterizes Proteus syndrome is progressive and tends to affect some tissues but not others. This can result in asymmetrical growth in the body such as the skull, bones, spine, hands, feet, fingers, and toes. Proteus syndrome often results in overgrowth of one side of the body and not the other. Benign tumors on the surface of the skin or inside the body may also occur. Raised brown patches on the skin and an overgrowth of tissues on the soles of the feet or the palms of the hands are common. The types of tissues and organs that are affected and the severity of the effects vary from person to person and within the course of a lifetime. Proteus syndrome is sometimes associated with mental delay.

KEY TERMS

Autosomal dominant—A pattern of genetic inheritance where only one abnormal gene is needed to display the trait or disease.

Benign tumor—An abnormal proliferation of cells that does not spread to other sites.

Chromosome—A microscopic thread-like structure found within each cell of the body that consists of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Connective tissue—A group of tissues responsible for support throughout the body; includes cartilage, bone, fat, tissue underlying skin, and tissues that support organs, blood vessels, and nerves throughout the body.

Cyst—An abnormal sac or closed cavity filled with liquid or semisolid matter.

Deoxyribonucleic acid (DNA)—The genetic material in cells that holds the inherited instructions for growth, development, and cellular functioning.

Gene—A building block of inheritance that contains the instructions for the production of a particular protein and is made up of a molecular sequence found on a section of DNA. Each gene is found at a precise location on a chromosome.

Mosaicism—A genetic condition resulting from a mutation, crossing-over, or nondisjunction of

chromosomes during cell division and causes a variation in the number of chromosomes in the cells.

Nevus (plural: nevi)—Any anomaly of the skin present at birth, including moles and various types of birthmarks.

Protein—Important molecules composed of amino acids that are involved in the formation of cellular structures and controlling the basic functions of the human body.

Spleen—Organ located in the upper abdominal cavity that filters out old red blood cells and helps fight bacterial infections. It is responsible for breaking down spherocytes at a rapid rate.

Spontaneous—Occurring by chance.

Thymus gland—An endocrine gland located in the front of the neck that houses and transports T cells, which are part of the immune system and help to fight infection.

Tissue—Group of similar cells that work together to perform a particular function. The four basic types of tissue include muscle, nerve, epithelial, and connective tissues.

Vascular malformation—Abnormality of the blood vessels that often appears as a red or pink patch on the surface of the skin.

Vertebra—One of the 23 bones that compose the spine. *Vertebrae* is the plural form of vertebra.

Genetic profile

The specific cause of Proteus syndrome is unclear. Proteus syndrome appears to occur randomly, which suggests that it is not inherited. Research shows that Proteus syndrome results from an unknown gene that is mutated in some cells but normal in other cells of the body. This type of gene expression is called mosaicism.

The tissues and organs that are affected in Proteus syndrome and the severity of effects can depend on how many cells contain the mutated gene and what types of cells contain it. Someone with many cells containing the changed Proteus gene is more likely to have more severe effects than someone with only a few affected cell types. Someone with many cells changed in a particular part of the body such as the hand are more likely to have excessive growth in that area. During fetal development, the

mutated Proteus gene will affect cell growth even after the fetus is fully formed, as cell division continues to take place and is necessary for the growth of tissues and organs and for the replacement of damaged cells. The mutated Proteus gene mainly results in excessive growth from infancy to adolescence.

Demographics

Only 100 to 200 cases of Proteus syndrome have been reported around the world. Both males and females are equally likely to be affected with Proteus syndrome.

Signs and symptoms

Individuals with Proteus syndrome can have a wide range of manifestations. The effects can also range from

mild to severe. The most common manifestations of Proteus syndrome include:

- overgrowth of hands, feet, fingers, or toes (gigantism)
- overgrowth of one side of the limbs, face, or body (hemihypertrophy)
- overgrowth of the connective tissue on the soles of the feet or palms of the hand or, less commonly, in the abdomen or nose (connective tissue nevi)
- darkened, discolored, and often rough or raised patches of skin (skin surface nevi)
- benign tumors on the skin surface and under the skin
- benign tumors of the fat cells (lipoma) or areas of significantly decreased or increased body fat
- abnormalities of the skull resulting in a large or asymmetrical head
- benign bony growths projecting outward from the ends of the bones (exostosis)

People with Proteus syndrome can have curvature of the spine. They may also have an enlarged spleen or thymus. Approximately 12%–13% of people with the disorder have cystic abnormalities of the lungs, which can interfere with the normal functioning of the lungs. Abnormalities in the blood vessels called vascular malformations appear as pink or red patches on the surface of the skin are common. About one-third of people with Proteus syndrome are mentally impaired; skull abnormalities are often seen in those with impairment. People with Proteus syndrome can have a distinctive facial appearance, with a long and narrow face, down-slanting eyes, wide and forward-tipping nostrils, a low nose bridge, and a mouth that remains open when at rest.

Sometimes mild or moderate effects of Proteus syndrome such as benign tumors are present at birth. As a person grows and develops, the tissue overgrowth progresses and changes. This progression is often irregular and is characterized by periods of major overgrowth and other periods of absent overgrowth. The effects therefore change over the course of a lifetime. However, most changes occur before adolescence since tissue overgrowth tends to plateau at that time.

Diagnosis

There is no blood test available to diagnose Proteus syndrome. A diagnosis can be made only by careful observation of the individual, perhaps over a period of time and through imaging studies. These may include x-ray evaluations of the skull and skeletal system; magnetic resonance imaging (MRI) of the limbs, nervous system, and abdomen; and computed tomography (CT) scans of the chest.

QUESTIONS TO ASK YOUR DOCTOR

- What are the physical symptoms typically associated with Proteus syndrome?
- How is Proteus syndrome diagnosed?
- What is the latest information from research studies about the progressions of Proteus syndrome?
- Are there organizations interested in providing information and support for people with Proteus syndrome and the general public?

The great variability of Proteus syndrome from person to person makes it hard to diagnose. There are no definitive and universal diagnostic guidelines.

Treatment and management

There is no cure for Proteus syndrome and treatment largely involves the management of effects of the disorder, such as the removal of tumors or bony overgrowths. Removal of tumors is not recommended unless they are causing major problems, since these tumors usually grow back. Surgery to remove an overgrown portion of the bone should be performed only if it affects normal functioning. Bony overgrowths in the ear, for example, may need to be removed if they are interfering with hearing. This type of surgery, however, can sometimes increase the growth of the remaining bone. Psychological counseling to help children with Proteus syndrome deal with the disorder should be considered. In order for counseling to be effective it is preferable that it begins at a young age.

Prognosis

The long-term prognosis of Proteus syndrome is not known. The life expectancy is likely to vary greatly in each occurrence of the syndrome. Those with tumors and bony overgrowths affecting critical organs are likely to have a poorer prognosis.

PRPS1 gene mutation— progressive hearing loss

Definition

The *PRPS1* gene encodes the instructions for producing an enzyme called phosphoribosylpyrophosphate synthetase 1 (PRPP synthetase 1). Although mutations (changes) in the *PRPS1* gene can cause several different syndromes, specific mutations cause a type of nonsyndromic, sensorineural, progressive hearing loss that primarily affects males. The disorder is nonsyndromic because it is not associated with any visible abnormalities in the external ear or with any other related medical problems. Sensorineural hearing loss is caused by malfunction of the cochlea of the inner ear. X-linked disorders are caused by mutations in genes, such as *PRPS1*, that are located on the X sex chromosome. They primarily affect males, because males have only one X chromosome. Females have two X chromosomes, so even if one X chromosome contains a mutated gene, a corresponding normal gene on the other X chromosome can often compensate for the mutation.

Description

More than 100 different genes have been associated with hereditary hearing loss and deafness, and it is expected that more hearing loss-associated genes will be identified in the future. Nonsyndromic progressive hearing loss caused by mutations in the *PRPS1* gene appears to be a rare form that is postlingual, meaning that the hearing loss develops after language acquisition.

The type of X-linked sensorineural nonsyndromic hearing loss (NSHL) caused by *PRPS1* gene mutations is also known as isolated X-linked sensorineural deafness, DFNX1 (for DeaFNess X-linked 1), or DFN2 because it was originally mapped to the DFN2 locus (site) on the X chromosome. Mutations in a second gene on the X chromosome, *POU3F4*, can also cause X-linked NSHL and were originally mapped to the DFN3 or DFNX2 locus. DFN3 hearing loss is a mixed type (a combination of conductive and sensorineural) and prelingual (occurring before language acquisition) and progresses to profound hearing loss. Mutations in a third gene on the X chromosome, *SMPX*, can cause postlingual, sensorineural, progressive NSHL that ranges from mild to profound. *PRPS1* gene mutations can also cause several different syndromes with multiple signs and symptoms that can include neurological problems and sensorineural hearing loss:

- Arts syndrome
- X-linked recessive Charcot-Marie-Tooth disease 5
- PRPP synthetase superactivity with PRPS-related gout

PRPP synthetase 1, produced by the *PRPS1* gene, is involved in making (synthesizing) phosphoribosylpyrophosphate (PRPP). PRPP is required to make new purine and pyrimidine nucleotides. These are the building blocks of the nucleic acids DNA and RNA, as well as ATP and GTP that are energy sources for cells. Cells can salvage or recycle purines and pyrimidines from the breakdown of DNA and RNA, which is much more energy efficient than producing new nucleotides. However, PRPP synthetase 1 and PRPP are also required for the purine salvage pathway. Sensorineural hearing loss, as well as the neurological symptoms of *PRPS1*-associated syndromes, is believed to result from reduced levels of GTP and possibly ATP, as well as other purine nucleotides. However, two other PRPS genes have been identified. *PRPS2* is also located on the X chromosome. *PRPS3*, located on chromosome 7, is believed to be active only in the testes.

Genetic profile

NSHL caused by *PRPS1* mutations is generally progressive and postlingual. However, the first family with NSHL that mapped to the DFN2 locus was a large, four-generational, British-American family with members who had congenital (present at birth and, therefore, prelingual) profound NSHL. The female carriers of mutations at the DFN2 locus had mild to moderate NSHL, especially at higher frequencies of sound. The second identified DFN2 family included five affected males with severe, progressive, postlingual hearing impairment in the low and middle frequencies and less impairment at high frequencies and with hearing loss first diagnosed

between the ages of seven and 20 years. This American family included two female carriers of the mutation with less severe hearing impairment. Since then, several large Chinese families have been identified with X-linked, postlingual NSHL mapping to the DFN2 locus. In 2010, researchers reported on a large, five-generational, Chinese family (106 members) with X-linked, mild-to-profound NSHL affecting 17 members. Nine affected males had progressive, severe to profound hearing loss beginning between the ages of five and 15. Seven of eight female carriers had mild to moderate hearing loss in one or both ears. Five of the women had hearing loss diagnosed between the ages of 47 and 64. One woman had severe to profound bilateral hearing loss at age 71. One female carrier had normal hearing at age 52. The researchers identified were able to identify an NSHL-associated mutation in the *PRPS1* gene.

The *PRPS1* gene is located on the long arm (q) of the X chromosome at Xq22.3. Mutations that cause progressive hearing loss in males and later-onset hearing loss in females have been identified as *PRPS1* gene mutations that change an amino acid within functional portions of the PRPP synthetase 1 protein and result in the loss of its enzymatic activity. Several identified NSHL-associated mutations change single nucleotides in the *PRPS1* gene sequence that result in changes in evolutionarily highly conserved amino acids in the enzyme. This means that many different organisms, including humans, have the same amino acids at these locations in the enzyme, indicating that these amino acids are very important for enzyme function.

Different mutations in the *PRPS1* gene that change different amino acids in the PRPP synthetase 1 enzyme have been identified as causing *PRPS1*-associated syndromes. PRPP synthetase 1 superactivity is caused by mutations that interfere with the regulation of the enzyme, resulting in *PRPS1*-related gout and, occasionally, neurological problems, developmental delay, and NSHL. Other *PRPS1* gene mutations that decrease PRPP synthetase I activity have been identified as causing Arts syndrome, which is characterized by intellectual disability, delayed motor development, and other serious problems in males, as well as NSHL. Females affected by Arts syndrome tend to have milder symptoms. Additional *PRPS1* gene mutations that change an amino acid in PRPP synthetase 1 have been identified as causing Charcot-Marie-Tooth X-linked neuropathy, which includes hearing loss and visual impairment. The *PRPS1* mutations that result only in progressive NSHL, although they change single amino acids in the enzyme, are not predicted to cause major structural changes in the PRPP synthetase 1 enzyme. This may explain why they cause only NSHL, in contrast to *PRPS1* mutations that may

KEY TERMS

Cochlea—The spiral-shaped, fluid-filled hearing apparatus of the inner ear.

Decibel (dB)—A logarithmic unit for expressing loudness or intensity; normal speech is typically in the range of 20–50 dB.

DFN2 or DFNX1—A DeaFNess gene locus associated with nonsyndromic, progressive, X-linked hearing loss, now identified as the *PRPS1* gene locus.

Hearing level (HL)—Hearing threshold; the sound level that can just barely be heard.

Hertz (Hz)—A measurement of sound frequency; 1 Hz equals to one cycle per second.

Nonsyndromic hearing loss (NSHL)—Hereditary hearing loss that is not part of another underlying genetic disorder.

Phosphoribosylpyrophosphate (PRPP)—A molecule that is required for making new purine and pyrimidine nucleotides and for salvaging and recycling purines; PRPP synthesis requires phosphoribosylpyrophosphate synthetase 1 (PRPP synthetase 1), which is encoded by the *PRPS1* gene.

Purines—Bases such as adenine and guanine; adenine and guanine nucleotides are building blocks of DNA and RNA, as well as ATP and GTP that are cellular energy sources and have other important roles in cellular function.

Sensorineural hearing loss—Hearing loss caused by an abnormality in or permanent damage to the inner ear, the auditory nerve, or the auditory center of the brain.

X-linked—A gene located on the X sex chromosome.

have much more severe effects on enzyme function and result in syndromes characterized by multiple neurological problems. Tests of *PRPS1* activity in cells from patients with X-linked progressive NSHL have indicated that PRPP synthetase 1 activity is reduced to approximately 50% of normal.

Demographics

The incidence of *PRPS1*-associated nonsyndromic progressive hearing loss in males is unknown, but it is presumed to be rare. Although more than 70% of hereditary hearing loss and deafness are nonsyndromic,

X-linked hearing loss and deafness accounts for less than 2% of NSHL and can be caused by genes other than *PRPS1*.

Signs and symptoms

The symptom of *PRPS1*-associated NSHL is postlingual, progressive, severe to profound, sensorineural hearing loss at all frequencies. In males, it appears to usually develop in childhood or adolescence. Female carriers of the *PRPS1* mutations may have no symptoms or have hearing loss that develops later in life.

Diagnosis

Genetic forms of hearing loss are diagnosed by an ear exam, hearing tests (audiometry), a physical exam, personal and family medical histories, imaging studies such as computed tomography (CT) scans of the temporal bone, and molecular genetic testing. NSHL is usually readily distinguishable from syndromic hearing loss by the absence of other signs and symptoms, which are usually neurological with *PRPS1*-associated syndromic hearing loss. Other diagnostic tests may include:

- auditory brain stem response testing to evoke responses in the auditory nerve and brain stem
- auditory steady-state testing
- evoked otoacoustic emissions to determine the activity of the outer hair cells of the cochlea
- acoustic immittance testing to assess the peripheral auditory system, including middle-ear pressure
- various specialized types of audiometry

Hearing is generally tested using earphones. Sounds are sent into the earphones at various decibel (dB) and frequency (hertz, Hz) levels to determine the amount of hearing loss in dB and the range of hearing loss in Hz. Each ear is tested independently, since hearing loss is not necessarily the same in both ears. Hearing loss is categorized by the hearing threshold or hearing level (HL)—the level of sound that can just barely be heard, measured in dB and defined as 0 dB for a healthy young adult with normal hearing.

- Normal hearing is an HL up to 25 dB.
- Mild hearing loss is an HL of 26–40 dB.
- Moderate hearing loss is an HL of 41–55 dB.
- Moderately severe hearing loss is an HL of 56–70 dB.
- Severe hearing loss is an HL of 71–90 dB.
- Profound hearing loss is an HL greater than 90 dB.

The average person speaking English in a conversational tone tends to speak in the 30–60 dB range, depending on the particular sounds. People with mild hearing

QUESTIONS TO ASK YOUR DOCTOR

- Why do you think my hearing loss is due to a *PRPS1* gene mutation?
- Is genetic testing available for *PRPS1* mutations?
- Should my family members be tested for *PRPS1* gene mutations or screened for hearing loss?
- What is the risk that I will pass on progressive hearing loss to my sons or daughters?

loss are generally able to hear and understand one-on-one conversations if they are close to the speaker, but they may have difficulty hearing a speaker who is far away, has a soft voice, or is surrounded by background noise. People with moderate hearing loss may have problems hearing conversational speech, even at relatively close range and in the absence of background noise. People with severe hearing loss have difficulty hearing in most situations, unless the speaker is talking loudly and is relatively close. People with profound hearing loss may not hear loud speech or environmental sounds.

Hearing loss is generally plotted on a graph called an audiogram of frequency versus HL. The normal hearing frequency range for humans is approximately 100–8,000 Hz. The normal frequency of sounds in English falls between approximately 240 Hz and 7,500 Hz. With progressive sensorineural hearing loss, any of the three frequency ranges (high, medium, or low) may be lost first.

A diagnosis of sensorineural rather than conductive or mixed hearing loss, the age of onset, and the degree of progressiveness, as well as a family history of hearing loss affecting younger males, may suggest *PRPS1*-associated NSHL. Sensorineural versus conductive hearing loss is distinguished using a device called a bone vibrator. The bone vibrator sends auditory signals through the bones of the ear, bypassing the ear canal and the ossicles of the middle ear. With conductive hearing loss, the affected individual can hear sounds at a lower dB level with the bone vibrator than with earphones, because the problem is in the outer or middle ear. With sensorineural hearing loss, the affected individual generally hears sounds through the bone vibrator at the same dB level as with earphones, because the problem lies within the inner ear, the auditory nerve, or the auditory center of the brain. The audio profile of hearing loss, as well as clinical presentation, can clearly distinguish NSHL associated with *PRPS1* mutations from NSHL caused by *POU3F4* mutations. Genetic testing

may be available for *PRPS1* mutations. Children who are at risk for hereditary hearing loss should have genetic testing, if possible, as well as regular screening audiometry.

Treatment and management

Most people with progressive NSHL benefit from hearing aids. Children over 12 months of age with severe to profound hearing loss may be candidates for cochlear implants. Regular audiologic examinations are used to measure the stability or progression of hearing loss and to identify any additional factors that may be contributing to hearing loss, such as middle ear problems. It is important for people with NSHL to avoid exposure to noise.

Prognosis

PRPS1-associated NSHL is generally progressive, meaning that hearing will continue to deteriorate. However, hearing aids can be very helpful.

Margaret Alic, PhD

Prune-belly syndrome

Definition

Prune-belly syndrome is characterized by the following three findings: lack of abdominal muscles, undescended testes, and abnormal development of the urinary tract. Also known as Eagle-Barrett syndrome, this rare disorder was first described in 1839.

Description

Prune-belly syndrome displays a wide range of severity. Affected individuals will have little to no muscle in their abdominal wall. The abdomen will appear wrinkled, like a prune. In male infants, the testicles, although present, are usually not seen. They remain inside the infant's abdomen instead of moving to the normal position during development of the fetus. Undescended testes are a risk factor for infertility and testicular cancer later in life.

There are a variety of urinary tract abnormalities that occur in this syndrome. The kidneys may not fully form, and the level of development of the kidneys varies. The ureters, the tubes that connect the kidneys to the bladder, may be very large. In the portions that are very large, urine may not be able to flow as well as normal. The bladder, the organ that holds urine, may also be very large. A connection between the umbilicus and bladder may be present as well. The urethra may have areas that are very dilated and others that are very narrow. The narrowing may not allow the urine to flow out well. This blockage causes the bladder to become very large. The drainage of the fetus's bladder is what makes up the amniotic fluid during pregnancy. If the bladder cannot be drained, then not enough amniotic fluid will be present. The lack of amniotic fluid, or oligohydramnios, can cause poor formation of the fetus's lungs. The bladder in these patients may become so large that a mass can be seen and felt on the baby.

Ten percent of cases may have various abnormalities of the heart or large blood vessels. A percentage of cases have abnormalities of the musculoskeletal system such as dislocation of the hips, abnormal indentation of the chest,

malformed feet or fingers, and a spine that is not aligned properly.

Genetic profile

A specific genetic defect is unknown. Multiple cases in families are rare but have been reported. The risk of recurrence in future pregnancies is unknown but is thought to be low.

Demographics

Despite the lack of a specific genetic defect or pattern of inheritance, over 95% of affected individuals are male. The incidence of this syndrome is estimated at 1 in 40,000 births.

Signs and symptoms

There are many symptoms that infants may experience in the newborn period. Most of these depend on the extent of damage that exists in the lungs and urinary tract. Infants who have poorly developed lungs may be unable to breathe on their own at birth. They may also develop a collapsed lung or pneumothorax. If the infant

KEY TERMS

Creatinine—A normal component of blood kept in low levels in urine by functioning kidneys.

Pyelonephritis—Inflammation of the kidney commonly caused by bacterial infections.

Ultrasound—An imaging technique that uses sound waves to help visualize internal structures in the body.

does not have a normal ribcage, then his or her ability to move air into and out of the lungs is impaired. This can lead to infections in the lung.

Since infants may not be able to eliminate all their urine, they are at risk of having repeated urinary tract infections.

Diagnosis

At birth, the syndrome is easily diagnosed based on the three findings that have been described. There is no specific

Eleven-month-old Lance Witterder has prune-belly syndrome, which means he has no abdominal muscles; the disorder also destroyed his kidneys. He underwent surgery to receive a kidney from his father. (ZUMA Press, Inc./Alamy)

QUESTIONS TO ASK YOUR DOCTOR

- How did this disorder get its name?
- What information is available about the genetic basis of this disease?
- What treatments are available for prune-belly syndrome, and what risks, if any, are associated with those treatments?

prenatal or genetic test that can diagnose prune-belly syndrome. The diagnosis of prune-belly syndrome can be made in the prenatal period by ultrasound, which can show some of the findings in this syndrome, such as distended bladder and ureters, oligohydramnios, and cryptorchidism. An enlarged bladder can be seen in other syndromes besides prune-belly; however, these findings on ultrasound should alert a physician to prune-belly as a possible cause.

Treatment and management

The potential treatments for prune-belly syndrome depend upon whether the diagnosis is made at birth or *in utero*. It also varies depending upon how severe the abnormalities are. Various surgical procedures have been performed on fetuses in an attempt to correct the urinary tract obstructions that occur. One of these procedures is the vesicoamniotic shunt. This procedure relieves bladder obstructions by placing a tube in the fetal bladder, allowing amniotic fluid to be produced as usual. The production of amniotic fluid allows for normal development of the lungs. There is not much information regarding the long-term outcomes for persons who receive these shunts. In infants who survive but have renal failure, kidney transplantation has been attempted with some success.

Prognosis

Approximately 20% of patients with this syndrome are stillborn. Thirty percent of infants do not survive past two years due to renal failure or infection. The remaining 50% of the infants will have a variety of urinary tract problems. Developing pyelonephritis (infection and inflammation of the kidney) at some point in time, having an elevated baseline creatinine, and having both kidneys look abnormal on an ultrasound are predictive for developing renal failure.

David Elihu Greenberg, MD

Pseudo-Gaucher disease

Definition

Pseudo-Gaucher disease is a rare lysosomal storage disease caused by a genetic mutation with characteristics very different from those of Gaucher disease, but caused by the same genetic mutation as that responsible for Gaucher disease. The condition is transmitted as an autosomal recessive trait. The disorder is also known as Gaucher-like disease and is also referred to as Gaucher, type IIIC and is distinct from Gaucher disease and its other subtypes due to the presence of neuropathy and cardiovascular calcifications.

Description

Pseudo-Gaucher disease is a well-studied genetic disorder transmitted as an autosomal recessive trait. It has a wide variety of manifestations, involving a number of different body systems. It is classified as the most common lysosomal storage disease caused by an abnormal accumulation of lipid glucocerebroside within lysosomes and macrophages, affecting a wide range of organs and body systems including the nervous system and the immune system. It has traditionally been divided into three major types, based on significant differences in those manifestations. Since the mid-1980s, a handful of cases have been reported in patients with some Gaucher-like symptoms, but other symptoms—especially cardiovascular calcification—that appear to justify its

KEY TERMS

Aortic valve—Valve joining the left ventricle to the aorta in the heart.

Arrhythmia—Irregular heartbeat.

Autosomal recessive—Genetic trait that appears only when two copies of a mutated gene are present.

Calcification—Accumulation of calcium minerals on soft tissues, causing them to become hard and rigid.

Enzyme—A protein that catalyzes biochemical changes in the body without itself undergoing permanent change.

Genotype—Genetic constitution of an organism for any given characteristic.

Mitral valve—Valve joining the left ventricle and left atrium in the heart.

Phenotype—Observable characteristic or trait of an organism.

Prevalence—Number of individuals living with a particular illness within a particular population at any given time. Prevalence is often expressed in terms of the number of individuals per 100 or per 1,000 members of the population.

classification as a distinct form of genetic disorder, now called Gaucher disease type IIIC, or pseudo-Gaucher disease.

Genetic Profile

Pseudo-Gaucher disease is caused by one or more mutations on the *GBA* (glucosidase, beta; acid [includes glucosylceramidase]) gene, the same gene that is responsible for other forms of Gaucher disease. The *GBA* gene is responsible for production of the enzyme beta-glucocerebrosidase, which catalyzes the breakdown of a large lipid molecule, glucocerebroside, into glucose and ceramide, a simpler lipid molecule. More than 200 mutations in the *GBA* gene have been implicated in the development of various forms of Gaucher disease. A specific mutation in the same gene has also been found to be associated with the development of pseudo-Gaucher disease. That mutation occurs at position 409 with the substitution of a histidine amino acid for aspartic acid. Although the genotypes of the four forms of Gaucher disease, types I, II, III, and IIIC (pseudo-Gaucher) are similar, the phenotypes produced are very different for the first three categories and pseudo-Gaucher.

Demographics

The prevalence of pseudo-Gaucher disease is roughly 1 in 50,000 to 1 in 100,000 people worldwide, with type I having a higher incidence. Type I occurs more frequently in the Jewish population of central and eastern European decent, affecting roughly 1 in 500 to 1 in 1,000 people of this Jewish population.

Signs and symptoms

The distinguishing characteristic of pseudo-Gaucher disease, as opposed to other forms of Gaucher disease, is cardiovascular calcification, primarily of the aortic and mitral valves. Neurological dysfunction of the eyes, resulting in corneal opacity, and enlargement of the spleen has also been observed in a small number of cases. Other signs of pseudo-Gaucher disease include skeletal abnormalities and seizures. Type 3 Gaucher disease is also distinguished from other types of Gaucher disease because it is a juvenile, chronic, and more mild form.

Diagnosis

The presence of cardiovascular insufficiency and ocular opacity are initial indications of the possibility of Gaucher-like disease. Further standard cardiac tests, such as diastolic murmur, cardiac enlargement, and arrhythmia, may suggest the presence of cardiovascular disease. A confirmatory test for the disorder consists of a genetic test for the presence of a mutation at position 409 in the *GBA* gene.

Treatment and management

No treatments are available for the cure of pseudo-Gaucher disease. Heart valve replacement has been attempted for the most severe cases of valve calcification, but generally without success. Three Spanish sisters who received this surgery all died, at the ages of 13, 15, and 16. Other forms of treatment include enzyme replacement therapy (ERT), which has had some success for other forms of Gaucher disease but not for pseudo-Gaucher disease because ERT is not capable of effecting anything across the blood-brain barrier, and therefore does not alter the effect the disease has on the brain and central nervous system.

Prognosis

Prognosis is generally poor for pseudo-Gaucher disease, since no successful treatment for manifestations of the disorder has been developed. A number of individuals with the disorder have died during childhood or adolescence, though recent data have shown those diagnosed with pseudo-Gaucher disease to live into the teenage years or early adulthood. No steps can be taken to prevent the occurrence of pseudo-Gaucher disease among individuals

QUESTIONS TO ASK YOUR DOCTOR

- What tests are available for diagnosing pseudo-Gaucher disease?
- Have any treatments been developed for extending the life of individuals with the condition?
- What is the status of gene therapy research for possible use with carriers of the mutation GBA gene?
- What type of Gaucher disease do I have, and what is my prognosis?

who carry the characteristic genotype. Early detection of the disease may make possible early intervention that may prolong the life of an affected individual.

Pseudoachondroplasia

Definition

Pseudoachondroplasia is moderately severe skeletal dysplasia characterized by disproportionate short stature, hypermobile joints, normal head size, and normal length and appearance at birth. Individuals with this condition are usually not diagnosed until early childhood. Complications of this disorder include early-onset arthritis of the weight-bearing joints and other orthopedic complications. This genetic disorder has autosomal dominant inheritance.

Description

Pseudoachondroplasia is a rare genetic skeletal dysplasia first described by Drs. Maroteaux and Lamy in 1959. It is sometimes also referred to as pseudoachondroplastic dysplasia and pseudoachondroplastic spondyloepiphyseal dysplasia and is one of more than 200 rare skeletal dysplasias. Skeletal dysplasias are a group of disorders that result from problems in bone growth and formation. The term "dwarfism" is losing favor to the more technical term of skeletal dysplasia. There are many causes of growth problems, including hormone imbalances, metabolic problems, and problems with bone growth.

Pseudoachondroplasia is one of the most common skeletal dysplasias. Individuals with pseudoachondroplasia have normal growth parameters (height and weight) at birth, and it usually is not until the second year of life that growth retardation becomes evident. During this phase, their body proportions resemble those of individuals with achondroplasia—the most common form of skeletal dysplasia. Because of this resemblance, this type of skeletal dysplasia was termed "pseudo" achondroplasia.

As the name implies, pseudoachondroplasia was once thought to be closely related to achondroplasia. However, geneticists have since learned otherwise. In appearance, individuals with pseudoachondroplasia share the same height as those with achondroplasia, but their head size is the same as that of average-size people, and they lack the distinct facial features characteristic of achondroplasia. Children with pseudoachondroplasia are usually not diagnosed until they are two or three years old when their growth parameters become abnormal. The most serious complications of pseudoachondroplasia are short stature, orthopedic problems, and early-onset osteoarthritis of the weight-bearing joints. Many individuals with pseudoachondroplasia experience significant joint pain and undergo multiple orthopedic surgeries and joint replacements.

Pseudoachondroplasia is easily recognizable. Individuals with pseudoachondroplasia have disproportionate short stature, a normal-sized head, normal facial features, joint laxity, and disproportionate shortening of their limbs. Most individuals with pseudoachondroplasia have a normal IQ. The early motor development of infants with pseudoachondroplasia is normal until the advent of walking when a waddling gait is often noted. Individuals with pseudoachondroplasia can have medical complications that range from mild to severe. Because of the differences in their bone structure and their joints, they are at increased risk to develop osteoarthritis at an early age (sometimes in their teens and usually by their 20s). They also have a small risk for neurologic problems caused by spinal cord compression due to abnormal vertebra and joint laxity.

The short stature of pseudoachondroplasia can be socially isolating and physically challenging. Most public places are not adapted to individuals of short stature, and this can limit their activities. Children and adults with pseudoachondroplasia can be socially ostracized due to their physical appearance. Many individuals erroneously assume that people with pseudoachondroplasia have limited abilities.

Genetic profile

Pseudoachondroplasia is caused by a mutation, or change, in the cartilage oligomeric matrix protein 3 gene (*COMP*) that is located on the short arm of chromosome 19 (19p13.1).

Genes contain the instructions that tell a body how to form. They are composed of four different chemical bases: adenine (A), thymine (T), cytosine (C), and guanine (G). When these bases are arranged in a specific order, they provide the instructions that a cell needs to form a protein. Every three bases codes for one amino acid. Amino acids are the building blocks of proteins.

The *COMP* gene provides the instruction for the formation of a particular protein that is made by cartilage cells and is then transported into the cellular matrix surrounding these cells. Cartilage plays a very important role in bone formation. Because of abnormalities in the formation of this protein, the protein cannot be transported out of the cell. This results in a deficiency of the protein in the cartilage matrix and a build-up of the protein within the cartilage cells. This leads to the development of pseudoachondroplasia. Because cartilage plays a role in the normal growth and development of bones, any problems with cartilage will lead to problems with bone growth.

Pseudoachondroplasia is caused by mutations in the *COMP* gene. One specific mutation accounts for approximately 30% of the cases of pseudoachondroplasia. The

COMP gene comprises 757 amino acids. In a normal (nonmutated) gene, amino acid 372 codes for aspartic acid. In most individuals with pseudoachondroplasia, this amino acid has been deleted. Other mutations have been detected in the *COMP* gene, most of which are small substitutions or deletions of base pairs.

Mutations in the *COMP* gene are inherited in an autosomal dominant manner. Every individual has two *COMP* genes: one from their father and one from their mother. In an autosomal dominant disorder, only one gene has to have a mutation for the person to have the disorder. Most individuals with pseudoachondroplasia are born to parents with average stature. Their pseudoachondroplasia is the result of a *de novo*, or new, mutation. No one knows the cause of *de novo* mutations or why they occur so frequently in pseudoachondroplasia. However, once a couple has had a child with pseudoachondroplasia, there is a 4% recurrence risk to have a second similarly affected child. This increased recurrence risk is due to germline mosaicism, or the chance that the *de novo* mutation is present in others of their sperm and egg cells.

An individual with pseudoachondroplasia has a 50% chance of passing on their mutated gene to their children. Often individuals with short stature will marry other individuals with short stature. If the partner of a person with pseudoachondroplasia also has an autosomal dominant inherited skeletal dysplasia, then there is a 25% chance that they will have a child with average stature, a 25% chance that they will have a child with one pseudoachondroplasia gene (a heterozygote), a 25% chance that their child will have the other autosomal dominant skeletal dysplasia (a heterozygote), and a 25% chance that a child will get a double dose of the gene for pseudoachondroplasia and the gene for the other skeletal dysplasia (a double heterozygote). Babies with two skeletal dysplasias (double dose) can be much more severely affected than babies with a single pseudoachondroplasia gene. Couples with skeletal dysplasias should seek genetic counseling to understand their exact risks before undertaking a pregnancy.

Demographics

The exact prevalence of pseudoachondroplasia is unknown, but it is estimated to occur in about 1 in 30,000 individuals. Pseudoachondroplasia affects males and females in equal numbers. Most individuals with pseudoachondroplasia are born to parents with average stature. This is due to a new mutation that occurs on the *COMP* gene of the child with pseudoachondroplasia.

Signs and symptoms

Individuals with pseudoachondroplasia have disproportionate short stature, normal-sized heads, limb

differences, and rhizomelic shortening of their limbs; rhizomelic means “root limb.” Rhizomelic shortening of the limbs means that those segments of a limb closest to the body (the root of the limb) are more severely affected. In individuals with pseudoachondroplasia, the upper arms are shorter than the forearms, and the upper leg (thigh) is shorter than the lower leg.

In addition to shortened limbs, individuals with pseudoachondroplasia have other characteristic limb differences. They have a limited ability to rotate and extend their elbows. They also have joint laxity, particularly of the hands, ankles, and knees. Because of this joint laxity, they can be bow-legged or knock-kneed and may have in-turned toes. Their hands and feet are short and broad, as are their fingers and toes. Their fingers and other joints are hyperextensible, or very flexible.

In addition to limb differences, individuals with pseudoachondroplasia have other characteristic skeletal differences. Because of malformed vertebra and lax ligaments, individuals with pseudoachondroplasia can have spinal problems, including kyphosis (hunchback), lordosis (swayback), and scoliosis.

Individuals with pseudoachondroplasia have normal facial features and a normal-sized head. This is one of the major features that differentiate pseudoachondroplasia from achondroplasia. Individuals with pseudoachondroplasia have shortening of their long bones. The average adult height of individuals with pseudoachondroplasia ranges from 32–52 in. (80–130 cm).

Diagnosis

Pseudoachondroplasia is diagnosed by a combination of physical exam, x-rays, and molecular testing. The characteristic findings of short stature and rhizomelic shortening of the limbs become apparent around two years of age and become more pronounced over time. In addition to being diagnosed by physical examination, individuals with pseudoachondroplasia have some specific bone changes that can be seen on an x-ray. A DNA blood test to look for mutations in the *x* gene may also help clarify the diagnosis.

Unlike other skeletal dysplasias, pseudoachondroplasia cannot be diagnosed by a prenatal ultrasound or sonogram because the characteristic changes in the bones and the growth delays do not appear until the child is two years of age.

The diagnosis of pseudoachondroplasia can be made prenatally by DNA testing if the mutation for that family has been characterized. A sample of tissue from a fetus is obtained by either chorionic villi sampling (CVS) or by amniocentesis. Chorionic villi sampling is generally done between ten and 12 weeks of pregnancy, and

amniocentesis is done between 14 and 18 weeks of pregnancy. Chorionic villi sampling involves removing a small amount of tissue from the developing placenta. The tissue in the placenta contains the same DNA as the fetus. Amniocentesis involves removing a small amount of fluid from around the fetus. This fluid contains some fetal skin cells from which DNA can be isolated. The fetal DNA is then tested to determine if it contains the mutation that is responsible for pseudoachondroplasia in that family.

Prenatal DNA testing for pseudoachondroplasia is not routinely performed in low-risk pregnancies. This type of testing is generally limited to high-risk pregnancies, such as those in which both parents have pseudoachondroplasia or one in which one parent has pseudoachondroplasia and the other parent has another autosomal dominant form of skeletal dysplasia. It is particularly helpful in determining if a fetus has received two dominant skeletal mutations. Infants who have inherited two autosomal dominant skeletal dysplasias may have very severe complications that may result in death.

DNA testing can also be performed on blood samples from children or adults. This is usually done as part of a genetic work-up to establish the exact form of skeletal dysplasia. Many skeletal dysplasias can be hard to differentiate from one another, and DNA testing can often clarify the diagnosis.

Treatment and management

There is no cure for pseudoachondroplasia. All children with pseudoachondroplasia should have their height, weight, and head circumference measured and plotted on growth curves specifically developed for children with pseudoachondroplasia. The most common medical complication is early-onset osteoarthritis and other orthopedic problems. Some patients experience significant pain that can be controlled by analgesics, although the effectiveness of various forms of analgesics has not been thoroughly studied in pseudoachondroplasia. Early-onset osteoarthritis is caused by malformations of the weight-bearing joints and deficient cartilage production. Approximately 50% of patients with pseudoachondroplasia will require hip replacements. By being aware of the potential medical complications and by taking some preventative measures, it may be possible to avoid or delay the onset of some of the long-term consequences of these complications.

Weight management is extremely important for an individual with pseudoachondroplasia. Excess weight can exacerbate many of the potential orthopedic problems, such as bowed legs, curvature of the spine, and joint and lower back pain. Excess weight can also contribute to sleep apnea problems. Development of good eating habits and appropriate exercise programs should

KEY TERMS

Rhizomelic—Term meaning “root limb,” which refers to the disproportionate shortening of the upper part of a limb compared to the lower part.

be encouraged in individuals with pseudoachondroplasia. However, because of the potential for spinal cord compression, care should be used in choosing appropriate forms of exercise.

The social adaptation of children with pseudoachondroplasia and their families should be closely monitored. Children with visible physical differences can have difficulties in school and socially. Support groups such as Little People of America can be a source of guidance on how to deal with these issues. It is important that children with pseudoachondroplasia not be limited in activities that pose no danger. In addition to monitoring their social adaptation, every effort should be made to physically adapt their surroundings for convenience and to improve independence. Physical adaptations can include step stools to increase accessibility and lowering of light switches and counters.

The two treatments that have been used to try to increase the final adult height of individuals with pseudoachondroplasia are limb-lengthening and growth hormone therapy.

Limb-lengthening involves surgically attaching external rods to the long bones in the arms and legs. These rods run parallel to the bone on the outside of the body. Over a period of 18–24 months, the tension on these rods is increased, which results in the lengthening of the underlying bone. This procedure is long, costly, and has potential complications, including pain, infections, and nerve problems. Limb-lengthening can increase overall height by 12–14 in. (30.5–35.6 cm) in some skeletal dysplasias. It does not change the other physical manifestations of pseudoachondroplasia, such as the appearance of the hands and feet. This is an elective surgery, and individuals must decide for themselves if it would be of benefit to them. The optimal age to perform this surgery is not known.

Growth hormone therapy has been used to treat some children with pseudoachondroplasia. Originally, there was doubt about the effectiveness of this treatment because children with pseudoachondroplasia are not growth-hormone deficient. This doubt has proven to be

justified. While this treatment seems to have some success for individuals with other forms of skeletal dysplasia, at least one study has found that it actually decreases the height of children with pseudoachondroplasia. Growth hormone therapy is not recommended for pseudoachondroplasia.

Prognosis

The prognosis for most people with pseudoachondroplasia is very good. In general, they have minimal medical problems, normal IQ, and most achieve success and have a long life, regardless of their stature. The most serious medical barriers to an excellent prognosis are the orthopedic complications and early-onset arthritis that can limit the activities of an individual and cause significant pain. Most individuals with pseudoachondroplasia will have multiple orthopedic surgeries over their lifetime.

Successful social adaptation plays an important role in the ultimate success and happiness of an individual with pseudoachondroplasia. It is very important that the career and life choices of an individual with pseudoachondroplasia not be limited by preconceived ideas about their abilities.

Pseudoxanthoma elasticum

Definition

Pseudoxanthoma elasticum (PXE) is an inherited connective tissue disorder in which the elastic fibers present in the skin, eyes, and cardiovascular system gradually become calcified and inelastic.

PXE was first reported in 1881 by Rigal, but the problem with elastic fibers was described in 1896 by Darier, who gave the condition its name. PXE is also known as Grönblad-Strandberg-Touraine syndrome and systemic elastorrhexis.

Description

The course of PXE varies greatly between individuals. Typically, it is first noticed during adolescence as yellow-orange bumps on the side of the neck. Similar bumps may appear at other places where the skin bends a lot, like the backs of the knees and the insides of the elbows. The skin in these areas tends to get thick, leathery, inelastic, and acquire extra folds. These skin problems have no serious consequences, and for some people, the disease progresses no further.

Bruch's membrane, a layer of elastic fibers in front of the retina, becomes calcified in some people with PXE. Calcification causes cracks in Bruch's membrane, which can be seen through an ophthalmoscope as red, brown, or gray streaks called angioid streaks. The cracks can eventually (e.g., in ten to 20 years) cause bleeding, and the usual resultant scarring leads to central vision deterioration. However, peripheral vision is unaffected.

Arterial walls and heart valves contain elastic fibers that can become calcified. This leads to a greater susceptibility to the conditions that are associated with hardening of the arteries in the normal aging population—high blood pressure, heart attack, stroke, and arterial obstruction—and, similarly, mitral valve prolapse. Heart disease and hypertension associated with PXE have been reported in children as young as four to 13 years of age. Although often appearing at a younger age, the overall incidence of these conditions is only slightly higher for people with PXE than it is in the general population.

Arterial inelasticity can lead to bleeding from the gastrointestinal tract and, rarely, acute vomiting of blood.

Genetic profile

PXE is caused by changes in the genetic material, called mutations, which are inherited in either a dominant or recessive mode. A person with the recessive form of the disease (which is most common) must

possess two copies of the PXE gene to be affected, and, therefore, must have received one from each parent. In the dominant form, one copy of the abnormal gene is sufficient to cause the disease. In some cases, a person with the dominant form inherits the abnormal gene from a parent with PXE. More commonly, the mutation arises as a spontaneous change in the genetic material of the affected person. These cases are called “sporadic” and do not affect parents or siblings, although each child of a person with sporadic PXE has a 50% risk to inherit the condition.

Both males and females can develop PXE, although the skin findings seem to be somewhat more common in females.

The actual genetic causes of this condition were not discovered until 2000. The recessive, dominant, and sporadic forms of PXE all appear to be caused by different mutations or deletions in a single gene called *ABCC6* (also known as *MRP6*), located on chromosome 16. Although the responsible gene has been identified, how it causes PXE is still unknown.

Genetic researchers have since identified mutations in a number of persons with PXE, most of whom have been found to have the recessive type. Affected individuals in these families had mutations in both copies of the gene and parents, who are obligate carriers, had a mutation in only one copy. Contrary to the usual lack of symptoms in carriers of recessive genes, some carriers of recessive PXE have been found to have cardiovascular symptoms typical of PXE.

Although the recessive type is the most common, there are also familial and sporadic cases that have been found to be caused by dominant mutations in the *ABCC6* gene.

Light micrograph of PXE. This disease causes the elastic fibers in the skin, eyes, and cardiovascular system to become calcified. (Biophoto Associates/Science Source)

Demographics

PXE is rare and occurs in about 1 in every 50,000 people in the general population. PXE is twice as common in females as in males.

Signs and symptoms

A wide range in the type and severity of symptoms exists between people with PXE. The age of onset also varies, although most people notice initial symptoms during adolescence or early adulthood. Often, the first symptoms to appear are thickened skin with yellow bumps in localized areas such as the folds of the groin, arms, knees, and armpits. These changes can also occur in the mucous membranes, most often in the inner portion of the lower lip. The appearance of the skin in PXE has been likened to a plucked chicken or Moroccan leather.

Angioid streaks in front of the retina are present in most people with PXE and an ophthalmologic examination can be used as an initial screen for the condition. Persons with PXE often complain of sensitivity to light. Because of the progressive breakdown of Bruch's membrane, affected persons are at increased risk for bleeding and scarring of the retina, which can lead to decreased central vision but does not usually cause complete blindness.

Calcium deposits in the artery walls contribute to early-onset atherosclerosis, and another condition called claudication, inadequate blood flow that results in pain in the legs after exertion. Abnormal bleeding, caused by calcification of the inner layer of the arteries, can occur in the brain, retina, uterus, bladder, and joints but is most common in the gastrointestinal tract.

Diagnosis

The presence of calcium in elastic fibers, as revealed by microscopic examination of biopsied skin, unequivocally establishes the diagnosis of PXE.

Treatment and management

PXE cannot be cured, but plastic surgery can treat PXE skin lesions, and laser surgery is used to prevent or slow the progression of vision loss. Excessive blood loss due to bleeding into the gastrointestinal tract or other organ systems may be treated by transfusion. Mitral valve prolapse (protrusion of one or both cusps of the mitral heart valve back into the atrium during heartbeat) can be corrected by surgery, if necessary.

Measures should be taken to prevent or lessen cardiovascular complications. People with PXE should control their cholesterol and blood pressure and maintain normal weight. They should exercise for cardiovascular

KEY TERMS

Angioid streaks—Gray, orange, or red wavy branching lines in Bruch's membrane.

Bruch's membrane—A membrane in the eye between the choroid membrane and the retina.

Carrier—A person who possesses a gene for an abnormal trait without showing signs of the disorder. The person may pass the abnormal gene on to offspring.

Claudication—Pain in the lower legs after exercise caused by insufficient blood supply.

Connective tissue—A group of tissues responsible for support throughout the body; includes cartilage, bone, fat, tissue underlying skin, and tissues that support organs, blood vessels, and nerves throughout the body.

Deletion—The absence of genetic material that is normally found in a chromosome. Often, the genetic material is missing due to an error in replication of an egg or sperm cell.

Dominant trait—A genetic trait where one copy of the gene is sufficient to yield an outward display of the trait; dominant genes mask the presence of recessive genes; dominant traits can be inherited from a single parent.

Elastic fiber—Fibrous, stretchable connective tissue made primarily from proteins, elastin, collagen, and fibrillin.

Gene—A building block of inheritance, which contains the instructions for the production of a particular protein, and is made up of a molecular sequence found on a section of DNA. Each gene is found on a precise location on a chromosome.

Mitral valve—The heart valve that prevents blood from flowing backward from the left ventricle into the left atrium. Also known as bicuspid valve.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and can be transmitted to offspring.

Recessive trait—An inherited trait or characteristic that is outwardly obvious only when two copies of the gene for that trait are present.

health and to prevent or reduce claudication later in life. They should also avoid the use of tobacco, thiazide anti-hypertensive drugs, blood thinners like Coumadin, and nonsteroidal anti-inflammatory drugs like aspirin and

QUESTIONS TO ASK YOUR DOCTOR

- What is the meaning of the name “pseudoxanthoma elasticum”?
- What is the probability that this genetic disorder will be transmitted from parents to children?
- On what basis is pseudoxanthoma elasticum syndrome diagnosed?
- What ongoing medical attention is needed to monitor the progress of this disease?

ibuprofen. In addition, they should avoid strain, heavy lifting, and contact sports, since these activities could trigger retinal and gastrointestinal bleeding.

People with PXE should have regular eye examinations by an ophthalmologist and report any eye problems immediately. Regular check-ups with a physician are also recommended, including periodic blood pressure readings.

Some people have advocated a calcium-restricted diet, but it is not yet known whether this aids the problems brought about by PXE. It is known, however, that calcium restriction can lead to bone disorders.

Prognosis

The prognosis is for a normal lifespan with an increased chance of cardiovascular and circulatory problems, hypertension, gastrointestinal bleeding, and impaired vision. Now that the gene for PXE has been identified, the groundwork for research to provide effective treatment has been laid. Studying the role of the *ABCC6* protein in elastic fibers may lead to drugs that will improve or prevent the problems caused by PXE.

Genetic tests are now available that can provide knowledge needed to both diagnose PXE in symptomatic persons and predict it prior to the onset of symptoms in persons at risk. Prenatal diagnosis of PXE, by testing fetal cells for mutations in the *ABCC6* gene, can be done in early pregnancy by procedures such as amniocentesis or chorionic villus sampling. For most people, PXE is compatible with a reasonably normal life, and prenatal diagnosis is not likely to be highly desired.

Genetic testing to predict whether an at-risk child will develop PXE may be helpful for medical management. A child who is found to carry a mutation can be monitored more closely for eye problems and bleeding

and can begin the appropriate lifestyle changes to prevent cardiovascular problems.

PTSD (post-traumatic stress disorder)

Definition

PTSD (post-traumatic stress disorder) is an anxiety disorder that develops as a result of exposure to traumatic event(s). Many different types of trauma can trigger PTSD, including sexual assault or abuse, combat, witnessing violence, terrorist attacks, natural disasters, serious injury or physical harm, or the threat of harm. Symptoms include startle responses, avoidance, nightmares, and/or sleep disturbances that continue for more than a month after the event. Researchers believe that genetic factors contribute about 20% to the risk of developing PTSD after experiencing trauma. There is much interest in identifying factors that affect PTSD susceptibility and that could be used, for example, in selecting combat personnel.

Description

PTSD was first defined as a diagnostic category by the American Psychiatric Association in 1980. It entered public awareness because of large numbers of affected combat veterans; however, it can be triggered by many types of traumatic events, including child abuse, plane or car crashes, bombings, or natural disasters such as earthquakes or floods.

PTSD results from a damaged or altered “fight-or-flight” response. This is a normal reaction to the threat of harm that prepares the body to protect itself by defense or avoidance. However, people with PTSD may continue to feel the fear or stress long after the danger has passed. Although changes in areas of the brain called the amygdala and the dorsal anterior cingulate cortex (dACC) are associated with PTSD, it is unclear whether these changes are causes or consequences. The amygdala and dACC are involved in fear and appear to be overactive in people who are susceptible to PTSD. The amygdala is involved in emotion, memory, and learning, including learning to fear (fear acquisition) and fear extinction when the threat has passed. The ventromedial prefrontal cortex (PFC) of the brain stores extinction memories and dampens the original fear response. “Hyperarousal” of these brain areas may contribute to the irritability and startle response that are symptoms of PTSD. Both genetic factors and experiences appear to contribute to this heightened activity. According to one model of PTSD, although characteristics of the amygdala and dACC contribute to PTSD susceptibility, following a traumatic event, changes occur in the PFC and its interactions with the hippocampus, a structure in the brain that is involved in memory formation. The PFC is involved in fear extinction, unlinking the signal from a threat once the threat is gone, and it helps sustain long-term extinction of the fear response. Studies suggest that in PTSD, the connection between these brain areas that extinguishes fear is impaired. This impairment may contribute to two other typical PTSD symptoms—the reliving of traumatic memories and the avoidance of anything or anyone that is a reminder of the traumatic event.

The development of PTSD appears to depend not only on the circumstances of the traumatic event but also on personal factors, including genetic factors. Several different genes have been directly associated with PTSD or with increased risk for PTSD or appear to interact with a history of childhood abuse to increase the risk of PTSD. Evidence also indicates that PTSD and other stress-related disorders may be associated with dysfunction of mitochondria—the energy-generating powerhouses of cells—or with epigenetic changes—chemical modifications to genes that do not change the DNA sequence of

the genetic material. The cell danger response (CDR) is a metabolic response of cells to a variety of threats, including psychological trauma, which are sensed by mitochondria and may persist in disorders such as PTSD after the threat is gone. Mitochondria have their own DNA (mtDNA). There are multiple copies of mtDNA in cells, and they have a high rate of mutation. As a result, mtDNA sequences can vary significantly, not only within an individual but even within single cells, and this can cause mitochondrial failure, which contributes to the CDR.

Childhood abuse and trauma are strong risk factors for stress-related disorders including PTSD. Childhood mistreatment, as well as PTSD, is associated with specific epigenetic changes that affect gene expression in the brain and other tissues. Childhood trauma, head injury, or other environmental factors may also affect brain growth, increasing the risk of PTSD in response to events later in life. Finally, personality and cognitive and social factors affect susceptibility to PTSD in response to trauma.

Genetic profile

Some genetic studies of PTSD have focused on genes that produce proteins involved in creating fear memories.

- Stathmin is a protein required for forming fear memories.
- Gastrin-releasing peptide (GRP) is a brain-signaling protein that is released during emotional events.
- There is a memory-enhancing variation of the gene encoding kinase C alpha, a protein that is important for the formation of emotional memories.
- A fear-enhancing version of the *5-HTTLPR* gene controls levels of serotonin—a neurotransmitter that affects mood.
- Low levels of a specific type of serotonin receptor appear to be associated with PTSD.
- A specific variant of a serotonin-transporter gene has been associated with increased risk for PTSD in women exposed to a traumatic event.
- The *ADCYAP1* gene, which produces pituitary adenylate cyclase-activating polypeptide, appears to be involved in stress responses. Variants in the receptor for this polypeptide have been linked to PTSD in women and increase stress following exposure to violence and the startle reflex in women and children.
- Other genes encoding receptors for stress hormones and immune-system signaling proteins have been linked to PTSD.

Researchers have identified links between certain variations in mitochondrial genes and full-blown PTSD. A variation in a single DNA base—called a single-nucleotide polymorphism (SNP)—that changes a single amino acid in the *MT-ATP8* gene that encodes subunit 8 of adenosine triphosphate (ATP) synthase, as well as an SNP in the *MT-ND5* gene that encodes subunit 5 of NADH dehydrogenase, have been associated with PTSD. The risk of PTSD increases with the increasing proportion of mitochondria that contain these genetic variants. Both ATP synthase and NADH dehydrogenase are involved in regulating the production of reactive oxygen species, which can increase mutation rates and may affect brain function, particularly in the PFC.

Epigenetic changes also appear to affect PTSD susceptibility. These changes, such as methylation (attachment of a methyl group, CH₃, to a DNA building block) can activate or silence gene activity to alter a protein produced in a cell. One study found that people with PTSD who were abused as children had distinct patterns of DNA methylation and gene activity (expression). Patients who had suffered childhood abuse had up to 12 times more epigenetic markers that affect gene expression compared to patients who were not maltreated as children. Furthermore, the study found that 98% of the changes in gene expression patterns differed between PTSD patients with and without a history of childhood abuse. In particular, patients who had experienced abuse had more changes in the expression of genes involved in nervous system development and immune system regulation; those without a history of abuse had more expression changes in genes associated with growth-rate regulation and cell death. Thus, PTSD may differ among people depending on whether they suffered childhood maltreatment.

Demographics

PTSD does not develop in most people who experience traumatic events. One study found that less than 2% of people exposed to a traumatic event developed full PTSD, although 8% developed partial PTSD. Nevertheless, PTSD can affect anyone at any age, especially combat veterans and survivors of physical devastation from war, natural disasters, or injuries and survivors of sexual, physical, or emotional abuse.

- More than 60% of men and 51% of women report having experienced at least one traumatic event, and 10% of men and 6% of women report four or more traumas.
- Every year, more than 1.25 million children of all ethnic and economic backgrounds in the United States, and at

KEY TERMS

Acute stress disorder (ASD)—An anxiety disorder similar to PTSD but with symptoms occurring immediately after a traumatic event and resolving within a month.

Amygdala—Any of the four basal ganglia in each cerebral hemisphere that are involved in triggering fear.

Cell danger response (CDR)—A metabolic response of cells to various types of threats.

Cognitive-behavioral therapy (CBT)—A type of psychotherapy that teaches people to recognize and change negative patterns of thinking and behavior.

DNA methylation—The addition of methyl groups (CH₃) to nucleotide bases of DNA to regulate gene expression.

Dorsal anterior cingulate cortex (dACC)—An area of the cerebral cortex that is involved in fear, mood disorders, and PTSD.

Epigenetic—A modification outside of the actual mutation of the DNA sequence, such as the addition of a methyl group.

Hippocampus—A part of the brain that is involved in learning and memory formation.

Hyperarousal—Symptoms of traumatic stress characterized by abnormally intense reactions, such as a heightened startle response.

Mitochondria—Organelles within the cell responsible for energy production.

Mitochondrial DNA (mtDNA)—A small set of genes in the mitochondria that are maternally inherited.

Prefrontal cortex (PFC)—The anterior gray matter of the frontal lobe of the brain that regulates complex cognition, emotions, and behaviors.

Serotonin—A neurotransmitter that transmits signals between nerve cells; low levels are associated with depression and PTSD.

Single-nucleotide polymorphisms (SNPs)—Single-nucleotide variant (SNV); a variation or point mutation in a single nucleotide building block of DNA.

least 40 million children worldwide, are abused or neglected.

- An estimated 10% of women and 5% of men will experience PTSD at some point in their lives.
- At some point in their lives, about 25% of Americans are involved in motor-vehicle accidents resulting in serious

injury, and an estimated 9% of survivors develop acute stress disorder (ASD) or PTSD.

- About 30% of Vietnam War veterans, 10% of veterans of the first Gulf War, and 15% of veterans of the wars in Iraq and Afghanistan have been diagnosed with PTSD.
- Survivors and bystanders of terrorist acts appear to be at particular risk for PTSD.
- Southeast Asians, especially refugees, have high rates of PTSD.
- Victims of violent crime, abused women and children, and victims of rape and female genital mutilation are at risk for PTSD.
- Some people can develop PTSD after a loved one experiences trauma or is harmed.
- Living in a depressed urban area or on a Native American reservation is a risk factor for PTSD.
- Boys—but not girls—residing in public housing in the United States who are subsequently moved to better neighborhoods experience increased rates of PTSD.
- One study found that almost 6% of people undergoing bereavement met the criteria for PTSD, especially if a loved one's death was sudden and unexpected.
- A history of mental illness is a PTSD risk factor.
- An estimated 1–2 surgical patients per 1,000 experience “anesthesia awareness” or “intraoperative recall,” in which they awake during surgery, and up to 70% of these people experience long-term stress, including PTSD, with rates five times higher than soldiers returning from Iraq and Afghanistan.
- A 2013 study found that 25% of survivors of a transient ischemic attack (TIA) or stroke develop PTSD within a year, and one in nine chronic PTSD.

Signs and symptoms

PTSD varies from minor to severe. Symptoms of ASD occurring immediately following a traumatic event and lasting less than a month are considered normal. PTSD symptoms may not develop for weeks, months, or even years after a traumatic event, but they usually begin within three months and last more than a month. Signs and symptoms of PTSD can include the following:

- flashbacks: repeatedly reliving the trauma, including physical symptoms of stress such as sweating or a racing heart
- frightening thoughts
- nightmares
- avoidance of reminders of the traumatic experience
- emotional numbness
- depression, guilt, or one or more anxiety disorders
- loss of interest in previously enjoyable activities

- difficulty remembering the traumatic event
- ongoing symptoms of hyperarousal, such as being easily startled, tenseness, anger, sleep difficulties, poor appetite, and/or poor concentration
- substance abuse
- suicidal behaviors

Symptoms of PTSD in young children can include the following:

- bedwetting
- being unable to talk or forgetting how to talk
- acting out the frightening event in play
- clinging to a parent or other adult

PTSD symptoms in older children and teens are usually similar to those in adults, but they may include disruptive, disrespectful, or destructive behaviors or thoughts of revenge.

Diagnosis

PTSD is diagnosed by a mental-health professional, such as a psychologist or psychiatrist, who may use psychological inventories or questionnaires. Diagnosis is based on the occurrence of all of the following symptoms lasting at least one month:

- at least one symptom of reliving the experience
- at least three avoidance symptoms
- at least two hyperarousal symptoms
- symptoms that interfere with daily life, including school or work, social relationships, and accomplishing important tasks

Treatment and management

PTSD should be treated by a mental-health provider experienced in dealing with the disorder. Different patients respond differently to various treatments, so multiple types of treatment may have to be tried. Concurrent problems—such as an abusive relationship, panic disorder, depression, or substance abuse—must be treated simultaneously. Traditional PTSD treatments include the following:

- antianxiety and sleep medications and antidepressants called selective serotonin reuptake inhibitors (SSRIs)
- individual psychotherapy or “talk” therapy
- group therapy
- support groups
- couples therapy
- neurofeedback or electroencephalographic (EEG) biofeedback
- specially designed video games
- support from family and friends

QUESTIONS TO ASK YOUR DOCTOR

- Do you think I have PTSD?
- What are the diagnostic criteria for PTSD?
- What treatment(s) do you recommend?
- Are there genetic screens for susceptibility to PTSD?

Cognitive-behavioral therapy (CBT) is often effective for PTSD. Cognitive restructuring therapy aims to help people process or make sense of bad memories. Stress inoculation therapy teaches methods for reducing anxiety. Exposure therapy or cognitive-processing therapy is a relatively new and often effective treatment for PTSD arising from recent trauma. The behavioral psychologist has the patient repeatedly recall and confront the traumatic event. With each recollection, the memory is edited through memory reconsolidation, and the details gradually become uncoupled from anxiety and panic attacks by a process called habituation. Repeated sessions may lead to extinction of the memory. However, exposure therapy is only effective for recent memories.

Prognosis

The prognosis for PTSD varies. Some people recover within six months, whereas others have symptoms lasting much longer or developing into a chronic condition.

Margaret Alic, PhD

Pulmonary arterial hypertension

Definition

Pulmonary arterial hypertension, also known as primary pulmonary arterial hypertension or familial pulmonary arterial hypertension (FPAH) when inherited, is a progressive disorder with abnormally high blood pressure that occurs in the pulmonary artery. This is due to narrowing and thickening of small pulmonary vessels from a genetic mutation. The pulmonary artery is the main artery, or blood vessel, that carries blood from the heart to the lungs. Pathology such as this leads to a decrease in cardiac output, followed by right-side heart failure and then death.

PAH may be idiopathic, meaning the type of pulmonary hypertension that occurs in people with no known family history of the disorder. In the past, PAH often was referred to as sporadic primary pulmonary hypertension.

Description

Pathology in the lungs that lead to pulmonary artery hypertension were first described in 1891. Changes occur that cause the small blood vessels in the lungs to become

Pulmonary hypertension is a type of high blood pressure that affects arteries in the lungs and heart. (Alila Medical Media/Shutterstock)

too narrow. When the vessels narrow, blood cannot travel through the lungs. This causes the heart to work harder to try to pump blood into the lungs. Eventually, the heart muscle weakens and loses its ability to pump effectively. Eventually, the heart may fail.

David Dresdale first noticed in 1954 that people in certain families were getting this uncommon disease. After identifying a mother, her sister, and a son with the same symptoms, other physicians began identifying families with the disease. In 1984, Jim Loyd and John Newman contacted patients and their family members to identify new cases. Their work eventually led to linkage studies.

Due to mutations in the genes that code for proteins responsible for the normal growth of smooth muscle that make up the walls of arteries, these arteries do not grow properly and therefore do not function properly.

Genetic profile

The genetic change linked to most families is due to an autosomal dominant pattern of inheritance for an alteration in the *TGF- β* (transforming growth factor beta) genes, which are important in the growth and proliferation of many different types of cells. These genes include *BMPT2* and *ENG*. *BMPT2* gene is located on chromosome 2 and helps regulate cell growth in the walls of the lungs' small arteries. Individuals receive a set of genes from each parent, so each individual receives a pair of

BMPT2 protein genes. If the copy of the *BMPT2* gene received from the mother or father is mutated, the child can develop PAH. As of 2015, studies had reported additional possible mutations that may lead to earlier and/or more severe forms of PAH and other genes that may contribute to PAH. These genes include but are not limited to *CAV1*, *EIF2AK4*, and *KCNK3*.

Researchers have identified more than 140 different mutations in the *BMPT2* gene that cause FPAH. Of the total number of cases of PAH, 75% of them are said to be due to a heterozygous mutation of this gene, and the remaining 25% is a sporadic mutation (not inherited). About one-half of these mutations change how the protein receptor forms, which reduces the amount of *BMPT2* protein in the cells. Others keep the receptor from reaching the cell surface or affect its structure so that the receptor cannot receive or send signals that help pulmonary artery wall growth.

Some people with PAH have major mutations in the *BMPT2* gene that have not been identified yet through gene sequencing. The likelihood that a person who has a *BMPT2* mutation will develop PAH is about 20%, but this likelihood varies among families. It is possible that *BMPT2* mutation is associated with genetic anticipation. This is a pattern in which a familial disease worsens with each generation.

In addition to the *BMPT2* mutation, scientists have discovered that some people with *ALK1* and *ENG* mutations, which cause Rendu-Osler-Weber syndrome, also are subject to pulmonary arterial hypertension.

Demographics

As of 2015, roughly 1,000 new cases of pulmonary arterial hypertension were diagnosed in the United States each year, and about one to three cases per one million people occurred throughout the world each year. Of these, about 15% could be attributed to the familial form. Yet PAH is not common; it occurs in only 1 in 100,000 to 1 in 1 million people. Women are affected 1.7 times as often as men, and most women are diagnosed between age 20 and 40. Race does not affect risk for this disease.

Signs and symptoms

Idiopathic pulmonary artery hypertension has no known cause, but several other conditions may be associated with it. PAH has been linked to an inherited genetic change, or mutation. There also is evidence to suggest that something happens to trigger PAH in a person who has the genetic markers and is susceptible to the disorder.

The increased pressure from the narrowed arteries in the lungs causes symptoms related to the heart and lungs.

Most people with PAH experience shortness of breath during exercise or other exertion. The other most common sign of pulmonary artery hypertension is fainting. As the condition becomes worse, the person may notice dizziness, chest pain, a racing pulse, and swelling of the ankles or lower legs. Some people even notice that their lips or skin turn a bluish color and notice increased weakness and fatigue.

Diagnosis

The symptoms of PAH and idiopathic pulmonary artery hypertension are similar to other common heart and lung conditions, including asthma, pneumonia, chronic obstructive pulmonary disease, and left heart failure. Because of this, PAH may be overlooked and difficult to diagnose, especially without information on family history.

Examination

During an examination, a physician will look for the symptoms and signs of pulmonary artery hypertension. For instance, the physician will use a stethoscope to listen to the heart valves and for a particular type of heart murmur that might indicate this condition instead of other heart and lung diseases. Other possible signs noted on the physical examination include swelling of the ankles and liver enlargement. A thorough medical history that includes family history of heart and lung disease provides clues to the diagnosis.

Tests

Usually, the physician will order a blood test to check oxygen levels in the blood, kidney and liver function, and for other possible causes of the symptoms, such as thyroid problems. These tests are not final diagnostic signs but tools to help lead to a diagnosis of FPAH.

Procedures

There are a number of procedures that might help lead to a diagnosis of FPAH, including the following:

- **Electrocardiogram.** A physician might use an electrocardiogram, or ECG, to look for changes that indicate thickening in the right side of the heart. Electrodes are stuck to the skin of the chest area and a recording of the electrical impulses is made on a machine.
- **Pulmonary function test.** This test is used to measure how much air the lungs can hold and exchange. The patient is asked to breathe in and hold the breath and then breathe out fast and hard. The test can be stressful but is helpful in gaining clues about how the lungs function and what might be causing the problems with the lungs' function.

KEY TERMS

BMPR2—Bone morphogenetic protein receptor 2; it is the gene on which a mutation occurs that is most responsible for cases of familial pulmonary arterial hypertension.

Hypertension—Abnormally high blood pressure in an artery.

Mutation—A change in a gene.

Pulmonary—Relating to the lungs; the pulmonary artery carries blood from the heart to the lungs.

- **Chest radiography.** A chest x-ray may not show signs of PAH but may be the first imaging examination the physician orders to look at the lungs. Imaging gives clues, such as enlargement of the right ventricle, that help diagnose PAH. The radiograph might show clues of other lung disease, which helps physicians decide causes of symptoms. There is exposure to a small amount of radiation.
- **Echocardiogram or Doppler echocardiogram.** This form of imaging uses sound waves instead of x-rays to create an image. The sonographer places a small transducer on the patient's chest to obtain images of the heart's chambers, the thickness of the wall of the right ventricle, and the heart's structure. Doppler echocardiograms can also measure blood flow and arterial pressure. Normally, the patient lies down for an echocardiogram. But the physician may want a measure of arterial pressure during exercise. In this case, the patient is asked to ride a stationary bicycle, and measurements of pressure are obtained while the patient is exercising. Echocardiograms are noninvasive, meaning they do not puncture the skin, and the sound waves are safe.
- **Computed tomography (CT) scan.** This technology uses x-rays that rotate around the body and take images that are like slices of a small part of the body being studied. Through the use of a computer and software, the images can be reconstructed to show 3-D views. They can provide great detail on changes in the right atrium and right ventricle. CT scanning is noninvasive, although it involves use of radiation.
- **Magnetic resonance imaging (MRI).** This technology uses very powerful magnets that rotate around the body to produce images in detail, especially soft tissues. MRI can help provide enough detail to measure pulmonary artery pressure. The procedure is not invasive and does not involve radiation but is more expensive than chest x-rays or CT scanning.
- **Cardiac catheterization.** This procedure can help directly measure pulmonary artery pressures to exclude other

causes. A physician who specializes in heart disease or a specially trained radiologist will guide a catheter, or long, flexible tube, into the pulmonary artery. The physician makes a tiny incision, usually in the groin area, and guides the wire up to the right side of the heart with the help of a monitor. This is an invasive procedure, but it is relatively safe with minimal pain, bleeding, or recovery time. It is the standard test used to confirm pulmonary artery hypertension.

- Lung biopsy. In rare cases of pulmonary artery hypertension, a lung biopsy may be needed to determine the cause of a patient's symptoms.

Other tests and procedures also may be used to help a physician diagnose pulmonary arterial hypertension and to determine that the disorder is caused by an inherited genetic mutation. Diagnosing FPAH involves ruling out other causes of a patient's symptoms. A classic example is the six-minute walk test, which measures an individual's ability to breathe while exercising. The person suspected of having FPAH may be asked to walk for up to six minutes and the distance the patient can complete in that time will be recorded. The actual tests used to help diagnose PAH vary depending on a patient's symptoms, knowledge of family history, age, and other factors.

Genetic testing

If a physician suspects that a patient has PAH, the patient may have genetic testing. A blood sample will be drawn and used to search for *BMPR2* mutations. The mutation is detected in about 80% of people with PAH. Genetic testing for *BMPR2* also may be used to predict if an adult family member is at risk for developing PAH. Guidelines suggest that family members of patients with PAH receive genetic testing for the disorder and genetic counseling when available. Generally, experts do not recommend genetic testing for PAH in children. The Pulmonary Hypertension Association maintains a list of centers that offer genetic testing and professional counseling for patients with pulmonary arterial hypertension and their families.

Treatment and management

Traditional

There is no cure for PAH but there are a number of options to treat the symptoms. A physician may prescribe drugs or therapies to help reduce the workload on the heart. Patients may need oxygen therapy as their disease progresses. Genetic testing and counseling may help guide family members of individuals with the mutation or support early clinical testing in family members. People who suspect or know they have PAH should avoid using certain medications that are known to increase risk of pulmonary artery hypertension, such as certain appetite-suppressant

QUESTIONS TO ASK YOUR DOCTOR

- What new treatments are available for the disorder?
- What can I do to slow the progression of the disease?
- Whom should I tell in my family so that they can be cautious or tested?

medications. They also should avoid use of cocaine, amphetamines, and related compounds. Some studies suggest that hormone replacement therapy for women and pregnancy may increase risk of onset of PAH.

Risk factors

Although there are risk factors for pulmonary arterial hypertension, the only risk factor for the familial form is to have the disease run in one's family, that is, to have genetic predisposition to the disease. By 2000, scientists had identified the genetic marker responsible for most cases of PAH.

Drugs

Endothelin receptor antagonists can control high levels of a hormone, which helps control blood flow and cell growth in the body's blood vessels. Phosphodiesterase-5 inhibitors help to relax muscles and reduce abnormal cell growth. Prostacyclins help relax blood vessels and prevent blood clots. Calcium channel blockers, diuretics, and anticoagulants may be prescribed to help prevent complications of PAH. Nitrous oxide (NO) therapy may also be a treatment option, as NO helps increase the diameter of the vessel via vasodilation, helping to get blood and oxygen to the tissues of the body more easily. The use of prostacyclins, however, is to date the most effective therapy for PAH. Researchers conduct clinical trials on a regular basis to test new therapies especially with genome sequencing giving light to the pathogenesis of many genetic disorders such as this.

Alternative

Potassium (20 mg per day) may help improve the heart muscle's ability to contract. Antioxidants such as vitamin E and vitamin C strengthen the immune system and may help protect the heart. Acupuncture may support traditional treatment by improving circulation.

Home remedies

Steam, especially with drops of essential oils, in a humidifier, vaporizer, or atomizer can stimulate respiration and circulation.

Prognosis

The prognosis for individuals with FPAH is poor. Although in rare instances, a person can die suddenly after a diagnosis and another can live decades, most people with the disorder become worse gradually. The average survival rate after diagnosis is 2.8 years.

Pyloric stenosis

Definition

Pyloric stenosis is caused by an enlargement of the pyloric sphincter muscle, which blocks the passage of food from the stomach to the intestines. This condition results in projectile vomiting, weight loss, and dehydration.

Description

Pyloric stenosis occurs due to enlargement of the pyloric sphincter, which is the ring of muscle at the outlet of the

KEY TERMS

Pyloric sphincter—Circular smooth muscle found at the outlet of the stomach.

Stenosis—The constricting or narrowing of an opening or passageway.

Ulcer—Inflammatory lesion of the mucous-like tissue in the stomach.

stomach that helps to control the emptying of food into the small intestine, where the digestion process continues. When the muscle cells of the pyloric sphincter become enlarged, the opening between the stomach and the small intestine (stenosis) enlarges, which blocks that passageway and causes food to be pushed back into the stomach.

Symptoms of pyloric stenosis typically appear two to six weeks after birth. In rare cases, it occurs in older adults, and when it does, it results from scarring from a chronic ulcer or hardening of the tissue at the outlet of the stomach. Alternate names associated with the disorder are hypertrophic pyloric stenosis and infantile hypertrophic pyloric stenosis. This entry will primarily focus on infantile pyloric stenosis.

Genetic profile

The exact cause of infantile pyloric stenosis is unknown. It appears to result from both environmental and genetic factors. Pyloric stenosis aggregates in families, and both siblings in identical twin pairs are more likely to have the condition than non-identical twins. Parents with pyloric stenosis are more likely to have children with the condition. Parents with one child with the condition have a higher risk for having another child with the condition, which suggests that genetic factors may predispose a child to pyloric stenosis.

It appears that there are many different genes involved in the development of pyloric stenosis. Pyloric stenosis is found in many different genetic conditions. Genetic studies have found possible associations between many different genes and pyloric stenosis. These genes each appear to increase the risk of this condition only slightly.

There are also environmental factors that appear to increase the risk of pyloric stenosis in infants. For example, use of macroline antibiotics such as erythromycin, early in pregnancy or in young infants, significantly increases the risk of pyloric stenosis. Being first-born, cesarean section delivery, preterm birth, and being bottle fed are also associated with the development of pyloric stenosis.

The opening from the stomach to the duodenum (the first part of the small intestine) is called the pylorus. Abnormal narrowing (stenosis) of this area is called pyloric stenosis (shown in inset). This is a condition that mostly affects babies, and results in projectile vomiting. Atropine can be used to treat the condition, but surgery is often needed in a procedure known as a pyloromyotomy. (Maurizio De Angelis/Science Source)

The association of erythromycin and pyloric stenosis may be related to the function of a protein called motilin produced in the small intestine. Motilin stimulates the contraction of muscles in the gastrointestinal system (gut). It binds to the motilin receptor in order to function. Erythromycin is a motilin receptor agonist, which means that it activates the receptor, which in turn activates motilin. This activity stimulates the pyloric sphincter muscle to contract repeatedly, which can cause it to enlarge, resulting in pyloric stenosis.

Demographics

About three out of every 1,000 babies born in the United States develop pyloric stenosis. It usually appears within three to four weeks after birth and rarely appears after three months. Pyloric stenosis affects males three to four times more often than females and appears to

occur more commonly in white people of northern European ancestry. It is, also more common in the first-born child. The risk to siblings, children and cousins of females with the condition is higher than for relatives of males with the condition.

Signs and symptoms

Symptoms include the following:

- Vomiting after feeding. Vomiting may become projectile (expelled with force), and vomit may have a “coffee ground” color. Vomit does not contain stomach bile, which is acidic and a brownish-green color. Bile-colored vomit would suggest that the infant has a condition other than pyloric stenosis.
- Olive-sized abdominal mass. A mass about the size of an olive may be felt in the upper abdomen. The mass should be hard, mobile, and non-tender.

These diagrams show the cross section of a normal pylorus in relation to a stomach with pyloric stenosis where the pylorus has become extremely narrowed. Constriction of the pylorus results from enlargement of the muscle surrounding it. (Gale)

- Pylorospasm (a spasm of the pyloric muscle may occur due to increased motility)
- Persistent hunger
- Dehydration
- Constipation
- Weight loss
- Decreased urination
- Rhythmic contraction of the stomach muscle (peristalsis)
- Irritability
- Prolonged sleepiness or sluggishness

Diagnosis

Pyloric stenosis is first diagnosed through a medical history and physical assessment. A palpable mass, the

size of an olive, in the upper abdominal area usually suggests a diagnosis of pyloric stenosis. When physical findings are inconclusive, an abdominal ultrasound or barium study may be performed to confirm diagnosis. An ultrasound, the preferred method of confirmation, is a noninvasive study that uses high-frequency sound waves to view internal structures of the body. A barium study involves the ingestion of a radiographic dye. The movement of the dye through the gastrointestinal (GI) tract can be followed by fluoroscopy or x-ray studies. The upper GI series may be an effective step in confirming pyloric stenosis. This test consists of aspirating (withdrawal of fluid) and measuring gastric contents. The amount of aspirated contents is indicative of pyloric stenosis; and studies have demonstrated this method to be a reliable diagnostic tool.

In adults with symptoms of pyloric stenosis, a barium swallow study is used to diagnose the disorder. X-rays are taken of the abdominal structures after the ingestion of the barium radioisotope (a radioactive form of a chemical element).

Treatment and management

Pyloric stenosis is usually treated by a surgical pyloromyotomy. The procedure involves making an incision into the pyloric muscle and spreading the walls of the muscle apart. This allows the membrane layer of the stomach to push up through the incision and relieve the blockage.

Blood analysis should be performed before surgery and intravenous fluids should be given to correct electrolyte (e.g., sodium, potassium, calcium) imbalances and rehydrate infants. Following surgery, the infant should start on an oral electrolyte solution such as Pedialyte. Feedings will be gradually increased until the infant is tolerating 2–3 oz. (60 ml) of breast milk or formula without complications. The stomach needs time to heal; therefore, vomiting due to increased feedings is common. Infants are usually discharged 24–48 hours following surgery. It has been suggested that rapid advancement of the strength and volume of feedings is effective and may allow for quicker discharge from the hospital.

Gastric peroral endoscopic myotomy surgery (G-POEM) has recently been used to treat pyloric stenosis. It is a less-invasive surgery that takes only 14 minutes rather than the two hours that pyloromyotomy takes. G-POEM involves applying an electrical current to the pyloric sphincter muscle, which helps to increase the passage of food from the stomach to the small intestine. This surgery is guided by endoscopy, which involves inserting a flexible tube with a camera at the end through the

QUESTIONS TO ASK YOUR DOCTOR

- How does pyloric stenosis affect the physiology of a child with the disorder?
- At what age, and by what means, is this disorder diagnosed?
- What treatments are available for pyloric stenosis, and how successful do those treatments tend to be?
- What is the prognosis for a child diagnosed with pyloric stenosis?

abdomen. It only requires a small hole, as compared to surgical pyloromyotomy, which requires a large incision.

Adults being treated for pyloric stenosis usually have a stomach tube inserted into the muscle that remains in place after surgery.

Recurrence of pyloric stenosis after surgery is rare. There has been no occurrence of conditions later in life related to the occurrence of pyloric stenosis during infancy.

Prognosis

The prognosis of pyloric stenosis is very good for those who are diagnosed early and treated with surgery. Life expectancy of infants diagnosed with pyloric stenosis is the same as that of the average individual. Parents should contact a doctor if pyloric stenosis is suspected.

Pyruvate carboxylase deficiency

Definition

Pyruvate carboxylase deficiency (PCD) is a rare non-sex-linked (autosomal) disorder that results from an insufficient amount of the enzyme pyruvate carboxylase. This disorder is inherited as a recessive trait and it is known to be caused by more than one different mutation in the same gene (allelic variants).

Description

There are two recognized types of pyruvate carboxylase deficiency: neonatal PCD (type B) and infantile-onset PCD (type A). Neonatal PCD is associated with a complete, or near complete, inability to produce pyruvate carboxylase. Infantile-onset PCD is associated with a chemical change in the pyruvate carboxylase enzyme that prevents this slightly different chemical from functioning as efficiently as the normal pyruvate carboxylase enzyme.

In order for the cells of the body to function properly, they must have energy. This energy comes in the form of the chemical ATP. ATP is primarily produced by

breaking down carbohydrates and blood sugar (glucose) molecules. To begin the process of converting glucose and carbohydrates into usable energy, these molecules are first converted into pyruvate molecules. Once pyruvate molecules have been formed, one of two things will happen: if more energy is required by the cell, the molecules will be further broken down into ATP; or, if no additional energy is needed by the cell, the pyruvate molecules will be put back together to reform a glucose molecule.

These transformations of pyruvate are accomplished primarily by two enzymes: pyruvate dehydrogenase (PDH), an enzyme that begins the breakdown of the pyruvate into ATP, and pyruvate carboxylase, an enzyme that begins the chemical process to reform glucose molecules. The reformation of glucose from pyruvate is a vital step in cellular metabolism. It allows carbohydrate molecules to be converted into a more readily usable form (glucose). Glucose is not only easier to break down into the energy required by the cells, but it is also more able to be transported through the bloodstream than most other fuel sources. This is particularly important because certain cells (primarily those of the brain and nervous system) cannot break down larger molecules; they must get their energy directly from glucose.

Pyruvate carboxylase is, in effect, part of the “off switch” for the production of ATP from pyruvate. After a cell has received the amount of ATP it requires, it is the job of pyruvate carboxylase to reconvert the excess pyruvate molecules in that cell back into glucose molecules for storage or transport to another part of the body where they may be needed. Any molecules that are not put back together will degrade into lactic acid. This lactic acid will either be released into the bloodstream or it will build up in the tissues. The build-up of lactic acid in the muscle tissues and red blood cells is normal during strenuous exercise. However, the accumulation of lactic acid in other tissues without exercise or without oxygen deprivation is symptomatic of an underlying problem in the normal metabolism of the cells.

People with PCD have either a complete inability or a severely limited ability to produce pyruvate carboxylase. Since these individuals cannot produce the amounts of this enzyme required to form glucose from pyruvate, this pyruvate is converted instead into lactic acid, which builds up in the cells. Additionally, since glucose cannot be adequately formed within the body of a pyruvate carboxylase-deficient individual, all the glucose required by the body must be ingested. This causes a glucose shortage that leads to low blood sugar (hypoglycemia) and a progressive degeneration of the tissues, with the

KEY TERMS

Allelic variants—A disease is said to have allelic variants when different mutations in the same allele result in identical, or nearly identical, symptoms. An allele is the combined locations of a gene on the two paired chromosomes that contain this gene.

Autosomal—Relating to any chromosome besides the X and Y sex chromosomes. Human cells contain 22 pairs of autosomes and one pair of sex chromosomes.

Biotin—A growth vitamin of the vitamin B complex found naturally in liver, egg yolks, and yeast.

Enzyme efficiency—The rate at which an enzyme can perform the chemical transformation that it is expected to accomplish. This is also called turnover rate. Individuals affected with type A PCD produce an enzyme that is much slower than the normal pyruvate carboxylase enzyme.

Necrotizing encephalomyelopathy—A progressive degeneration of the brain and central nervous system. This condition is fatal in nearly all individuals affected with type A pyruvate carboxylase deficiency.

Pyruvate carboxylase—The enzyme that is responsible for the first step in the conversion of pyruvate molecules into glucose molecules. Individuals with Type A PCD produce an highly inefficient form of pyruvate carboxylase. Individuals with Type B PCD either completely lack the ability to produce this enzyme, or they cannot produce it in sufficient quantities to sustain life.

most profound effects observed in the brain and central nervous system, since these tissues are the most reliant on the use of glucose for energy.

Pyruvate carboxylase is also important in the process that removes excess nitrogen from the body (the urea cycle). Since pyruvate carboxylase-deficient individuals do not have sufficient quantities of pyruvate carboxylase, they develop a build-up of nitrogen, in the form of ammonia, in the bloodstream and the tissues.

Genetic profile

The gene that is responsible for the production of pyruvate carboxylase has been localized to a small region of chromosome 11. There are at least three mutations in this gene that lead to type B PCD. There is only one known mutation that leads to type A PCD.

Both types of PCD are transmitted via a recessive trait, which means that both parents must be carriers of the mutation in order for it to occur in their children. In the case of parents with one child affected with PCD, the likelihood that a second child will be affected with PCD is 25%.

Demographics

PCD is estimated to occur in approximately 1 in every 250,000 live births, although the exact incidence of the disorder is unknown.

Type A PCD is also called North American PCD because it occurs almost exclusively in Algonquin-language-speaking Native North Americans. In the Micmac, Cree, and Ojibwa tribes of Canada, it is estimated that as many as one in ten individuals are carriers of the mutation that causes type A PCD. This suggests a founder effect in these populations. A founder effect is a genetic term that means a single individual brought a mutation into a subpopulation at a time when the subpopulation was quite small. As a result, a large majority of the members of the subpopulation carry the mutation derived through direct ancestry to this one individual.

Type B PCD is also called French PCD because it has a much higher incidence among the French than among any other subpopulation.

Signs and symptoms

Type A, or infantile-onset, PCD may be fatal prior to birth, or it may not present any symptoms until approximately three months of age. These individuals will show severe physical and mental delay. Additionally, children affected with type A PCD have a progressive degeneration of the entire brain and nervous system (necrotizing encephalomyelopathy) that eventually leads to death.

Type B, or neonatal, PCD is generally fatal prior to birth. In the rare instances of a liveborn child affected with type B PCD, severe growth delay (extremely low birth weight) and severe mental impairment are to be expected. Children born with type B PCD fail to thrive and generally do not survive past the first three months of life.

Diagnosis

PCD is diagnosed primarily through blood tests to determine the blood concentrations of lactate and pyruvate. Extremely high levels of both of these chemicals in the blood indicate that a congenital problem in cellular metabolism is most likely present. PCD is often differentiated from other cellular metabolic disorders by the

QUESTIONS TO ASK YOUR DOCTOR

- What does the term “pyruvate carboxylase” mean?
- How do type A and type B forms of this disorder differ from each other?
- What treatments are available for this disorder, and do the treatments differ for each type of the condition?
- What information can a genetic counselor provide about pyruvate carboxylase deficiency disorder?

extreme speed with which glucose levels in the blood drop during fasting (fasting hypoglycemia) and the abnormally low levels of the chemical aspartic acid in the blood.

PCD can be tested prenatally by measuring the activity of pyruvate carboxylase in chorionic villi samples.

Treatment and management

Administration of aspartic acid has been successful in decreasing the pyruvate and lactate concentrations in the blood of some PCD-affected individuals. However, this treatment does not repair the damage to the pyruvate carboxylase enzyme, so progressive degeneration of the nervous system is slowed only slightly and the outcome is still death.

Biotin (a B-complex vitamin) is a coenzyme to pyruvate carboxylase. It has been shown that type B PCD is responsive to treatment with biotin while type A is not. Therefore, in the rare instance of a liveborn child with type B PCD, life may be extended through the administration of biotin.

Prognosis

Without prenatal administration of enzyme replacement therapy (which is currently not available), in which the developing fetus is given an artificial form of pyruvate carboxylase, individuals affected with either type A or type B PCD will die either prior to birth or, generally, within the first six months of life. Without prenatal enzyme replacement therapy, most children affected with PCD are born with such brain and nervous system dysfunction that a decision has to be made about treatment to sustain life.

Pyruvate dehydrogenase complex deficiency

Definition

Pyruvate dehydrogenase complex deficiency (PDHA) is a genetic disorder that results in a malfunctioning of the Krebs, or tricarboxylic acid (TCA), cycle. It is sex-linked and appears to be a dominant trait.

Description

PDHA is one of the most common of the genetic disorders that cause abnormalities of mitochondrial metabolism. The mitochondria are the organelles inside cells that are responsible for energy production and respiration at the cellular level. One of the most important processes in the mitochondria is the TCA cycle (also known as the Krebs cycle). The TCA cycle produces the majority of the ATP (chemical energy) necessary for maintenance (homeostasis) of the cell. The production of this ATP is accomplished by chemically converting molecules of the chemical pyruvate into carbon dioxide, water, and ATP. After a blood sugar (glucose) molecule has been broken

down into two pyruvate molecules, one of two things will occur: if energy is required by the cell, the molecules will be further broken down into ATP, carbon dioxide, and water; or, if energy is not needed by the cell, the pyruvate molecules will be put back together to reform a glucose molecule. These transformations of pyruvate are accomplished primarily by two enzymes: pyruvate carboxylase, an enzyme that converts pyruvate molecules into oxaloacetate molecules in preparation to reform glucose molecules; and pyruvate dehydrogenase (PDH), an enzyme that begins the breakdown of the pyruvate into the eventual products of carbon dioxide, water, and ATP. To break down the pyruvate, PDH gets some help from two other enzymes: dihydrolipoyl transacetylase and dihydrolipoyl dehydrogenase. These three enzymes and the five coenzymes (CoA, NAD⁺, FAD⁺, lipoic acid, and TPP) that assist these enzymes are collectively known as the pyruvate dehydrogenase complex (PDH complex).

Individuals affected with PDHA have deficiencies in one or more of the three enzymes within the PDH complex. Most have a deficiency of the PDH enzyme itself. Tissues that require the greatest amounts of oxygen (highly aerobic tissues), such as those of the brain and the rest of the central nervous system, are most sensitive to deficiencies in the PDH complex.

People with PDHA have either a complete inability or a severely limited ability to produce PDH. Since these individuals cannot produce the amounts of PDH required to break down pyruvate, the cells cannot produce enough energy, in the form of ATP, to maintain themselves. This causes a progressive degeneration of the tissues, with the most profound effects observed in the brain and central nervous system.

PDH is an enzyme. An enzyme is a chemical that facilitates (catalyzes) the chemical reaction of another chemical or of other chemicals; it is neither a reactant nor a product in the chemical reaction that it facilitates (catalyzes). As a result, enzymes are not used up in chemical reactions; they are recycled. One molecule of an enzyme may be used to facilitate (catalyze) the same chemical reaction over and over again several hundreds of thousands of times. All the enzymes necessary for catalyzing the various reactions of human life are produced within the body by genes. Genetic enzyme deficiency disorders, such as PDHA, result from only one cause: the affected individual cannot produce enough of the necessary enzyme because the gene designed to make the enzyme is faulty. Enzymes are not used up in chemical reactions, but they do eventually wear out or accidentally get expelled. Also, as an individual grows, they may require greater quantities of an enzyme. Therefore, most enzyme deficiency disorders will have a time component

to them. Individuals with no ability to produce a particular enzyme may show effects of this deficiency at birth or shortly thereafter. Individuals with only a partial ability to produce a particular enzyme may not show the effects of this deficiency until their need for the enzyme, because of growth or maturation, has outpaced their ability to produce it.

The level of ability of the pyruvate dehydrogenase complex deficiency-affected individual to produce PDH, or his or her ability to sustain existing levels of PDH, are the sole determinants of the severity of the observed symptoms in that individual and the age of onset of these symptoms.

PDHA is the most common cause of non-exercise-related build-up of lactic acid in the tissues (primary lactic acidosis). When a tissue requires more energy than it can gain from aerobic processing (TCA cycle), it begins to break down carbohydrates, via an anaerobic process, in order to gain the necessary energy. Lactic acid is the by-product of carbohydrate metabolism. The build-up of lactic acid in the muscle tissues and red blood cells is normal during strenuous exercise. However, the accumulation of lactic acid in other tissues without exercise or without oxygen deprivation is symptomatic of an underlying problem in the normal aerobic process (TCA cycle).

Genetic profile

The gene responsible for PDHA has been mapped to Xp22.2-p22.1. This gene is now termed the *PDHA1* gene. At least 50 different mutations of this gene resulting in varying symptoms of PDHA have been identified. Because the gene for PDHA is on the X chromosome, it is called a sex-linked disease. PDHA shows a dominant inheritance pattern: therefore, females with only one affected X chromosome also exhibit symptoms of the disease.

Demographics

While the actual prevalence remains unknown, almost equal numbers of males and females have been identified as being affected with PDHA. Even though PDHA is known to be transmitted as a sex-linked dominant trait on the X chromosome, it is not necessarily lethal in affected males (who possess only a single X chromosome), because the symptoms of PDHA are quite different depending on the precise mutation responsible for the symptoms in each individual. The genetic mutations are linked to the sex of the affected individual. Affected live-born males tend to have minor (missense/nonsense-type) mutations, while affected females tend to have more major (insertion/deletion-type) mutations. The almost unobserved insertion/deletion-type mutations in males with PDHA suggests that these mutations are fatal to males with

KEY TERMS

ATP—Adenosine triphosphate. The chemical used by the cells of the body for energy.

Enzyme—A protein that catalyzes a biochemical reaction or change without changing its own structure or function.

Highly aerobic tissues—Tissue that requires the greatest amount of oxygen to thrive.

Hypotonia—Reduced or diminished muscle tone.

Lactic acid—The major by-product of anaerobic (without oxygen) metabolism.

Mitochondria—Organelles within the cell responsible for energy production.

Pyruvate dehydrogenase complex—A series of enzymes and co-factors that allow pyruvate to be converted into a chemical that can enter the TCA cycle.

TCA cycle—Formerly known as the Krebs cycle, this is the process by which glucose and other chemicals are broken down into forms that are directly useable as energy in the cells.

only a single X chromosome (homozygous males). Females with two X chromosomes, only one of which contains an insertion/deletion-type mutation (heterozygous females), and males with an extra X chromosome (XXY males) with this type of mutation on only one chromosome (heterozygous males) are affected with nonlethal forms of PDHA.

A fixed sequence difference between African and non-African samples of the *PDHA1* gene has been identified. That is, those of African descent carry a different version of the *PDHA1* gene than those of non-African descent. It has been established that these differences in the subpopulations arose more than 200,000 years ago, which predates the earliest known modern human fossils. This genetic evidence is interesting in that it suggests that the modern human emerged from already genetically divided subpopulations.

Signs and symptoms

PDHA affects primarily the brain and central nervous system. In individuals with extreme deficiencies of PDH, the brain may fail to reach normal size during fetal development, leading to a small brain and skull (microcephaly). Abnormal development of the cerebrum, cerebellum, and brain stem are the most common brain dysfunctions associated with PDHA. The normal hollow cavities (ventricles) within the brain are usually much

larger than normal (dilated) in individuals affected with PDHA. The connection between the left and right hemispheres of the brain (corpus callosum) is generally underdeveloped or completely absent as well.

A condition in which the normal insulating layer (myelin) that surrounds the neurons is either absent or insufficient (leukodystrophy) is observed in many individuals affected with PDHA. Some PDHA-affected individuals also have periods of brain malfunctioning in which the neurons within the cerebellum temporarily lose the ability to act in a coordinated fashion (cerebellar ataxia). These attacks of cerebellar ataxia generally last from a few days to a few weeks and reoccur every three to six months throughout life with decreasing severity after puberty. Lactic acid accumulation in the brain may also lead to breathing (respiratory) and kidney (renal) problems.

Some individuals affected with PDHA experience increased muscle tone in both legs (spastic diplegia) or in all four limbs (spastic tetraplegia) similar to that seen in the classic case of cerebral palsy. Seizures occur in almost all individuals affected with PDHA. A seizure is the result of sudden abnormal electrical activity in the brain. This electrical activity can result in a wide variety of clinical symptoms including muscle twitches; tongue biting; fixed, staring eyes; a loss of bladder control resulting in involuntary urination; total body shaking (convulsions); and/or loss of consciousness.

Unusual, or dysmorphic, facial features are sometimes associated with PDHA. These include a broad or upturned nose; low-set ears; downward-slanted eyes, drooping eyelids; and a staring or squinting appearance. Other physical symptoms of PDHA include short fingers and arms, urogenital malformations, low muscle tone (hypotonia), and feeding difficulties. Mental impairment is present in some cases. Delayed physical and motor development can also occur.

Diagnosis

Improper brain development in individuals with PDHA is observable in the womb via ultrasound or via MRI after birth, although brain malformations may result from any number of other factors. Babies born with PDHA may exhibit low birth weight, a weak suck, failure to thrive, lack of muscle tone, and unusual appearance of the head, face, and limbs. Convulsions, developmental delay, and eye problems may develop a few months after birth. A diagnosis of PDHA is generally confirmed with a blood test for severe lactic acidosis, an observance of deficient PDH activity in sampled or cultured fibroblasts, or by an observance of elevated amounts of lactate and pyruvate in the cerebrospinal fluid drawn in a spinal tap.

QUESTIONS TO ASK YOUR DOCTOR

- How is the normal biochemistry of a person with pyruvate dehydrogenase complex deficiency disrupted by the disease?
- Is gene replacement therapy a cure for this disease, and, if so, what are the risks involved?
- Are there prenatal tests for pyruvate dehydrogenase complex deficiency, and why would they be recommended or not recommended?
- Are there Internet sources from which I can get additional information about pyruvate dehydrogenase complex deficiency?

Treatment and management

Treatment of PDHA is on a case-by-case basis depending on the observed symptoms. These treatments may include early and continuing intervention programs for developmental delays and intellectual disability, anticonvulsants to control seizures, muscle relaxants to control spasticity, and/or surgery to release the permanent muscle, tendon, and ligament tightening (contracture) at the joints that is characteristic of longer-term spasticity.

A high-fat diet including beer as an alternative source of the chemical acetyl-CoA that is not produced in high enough supply because of the deficiency of PDH enzyme is often recommended for those individuals affected with PDHA. Dietary supplements of thiamine, lipoic acid, and L-carnitine have also proven beneficial in some cases.

Prognosis

The prognosis for PDHA-affected individuals varies widely with the severity of the symptoms. Until gene or enzyme replacement therapy becomes available, the most seriously affected individuals are not likely to receive relief from their symptoms and many will die at early ages. For those less seriously affected, several treatments are available to improve quality of life. Many less severely affected individuals live normal lifespan with their abilities and quality of life only limited by the degree of mental impairment and muscle spasticity that is present.

Pyruvate kinase deficiency

Definition

Pyruvate kinase deficiency (PKD) is part of a group of disorders called hereditary nonspherocytic hemolytic anemias. Hereditary nonspherocytic anemias are rare genetic conditions that affect the red blood cells. PKD is caused by a deficiency in the enzyme pyruvate kinase.

Description

In PKD, there is a functional abnormality with the enzyme pyruvate kinase. Usually, pyruvate kinase acts as a catalyst in the glycolysis pathway and is considered an essential component in this pathway. Glycolysis is the method by which cells produce their own energy. A problem with any of the key components in glycolysis can alter the amount of energy produced. In the red blood cells, glycolysis is the only method available to produce energy. Without the proper amount of energy, the red blood cells do not function normally. Since pyruvate kinase is one of the key components in glycolysis, when there is a problem with this enzyme in the red blood cells,

there is a problem with the production of energy, causing the red blood cells to not function properly.

There are four different forms of the pyruvate kinase enzyme in the human body. These forms, called isozymes, all perform the same function, but each isozyme of pyruvate kinase is structurally different and works in different tissues and organs. The four isozymes of pyruvate kinase are labeled M1, M2, L, and R. The isozyme M1 is found in the skeletal muscle and brain, isozyme M2 can be found in most fetal and adult tissues, isozyme L works in the liver, and isozyme R works in the red blood cells. In PKD, only the pyruvate kinase isozyme found in red blood cells, called PKR, is abnormal. Therefore, PKD affects only the red blood cells and does not directly affect the energy production in the other organs and tissues of the body.

Genetic profile

There are two PK genes and each gene produces two of the four isozymes of pyruvate kinase. The M1 and M2 isozymes are produced by the pyruvate kinase gene called *PKM2* and pyruvate kinase isozymes, L and R, are products of the pyruvate kinase gene, *PKLR*. The *PKLR* gene is located on chromosome 1, on the q arm (the top half of the chromosome), in region 21 (written as 1q21). There have been over 125 different mutations described in the *PKLR* gene that have been detected in individuals with PKD.

PKD is mainly inherited in an autosomal recessive manner. There have been a few families where it appeared that PKD was inherited in either an autosomal dominant manner or where the carriers of PKD exhibited mild problems with their red blood cells. As with all autosomal recessive conditions, affected individuals have a mutation in both pairs of genes. Most individuals with PKD are compound heterozygotes, meaning that each *PKLR* gene in a pair contains a different mutation. There are individuals who have the same mutation on each *PKLR* gene, but these individuals tend to be children of parents who are related to each other.

There are three mutations in the *PKLR* gene—*1529A*, *1456T*, and *1468T*—that are seen more frequently in individuals with PKD than the other mutations. The mutation *1529A* is most frequently seen in Caucasians of northern and central European descent and is the most common mutation seen in PKD. The mutation *1456T* is more common in individuals of southern European descent and the mutation *1468T* is more common in individuals of Asian descent.

For most of the mutations seen in the *PKLR* gene, no correlation between the specific mutation and the severity of the disorder has been observed. However, for two of

the mutations, there has been speculation on their effect on the severity of PKD. When the mutation *1456T* has been seen in the homozygous state (when both *PKLR* genes contain the same mutation), those rare individuals experienced very mild symptoms of PKD. Also, there have been individuals who were homozygous for the *1529A* mutation. These individuals had a very severe form of PKD. Therefore, it is thought that the *1456T* mutation is associated with a milder form of the disease and the *1529A* mutation is associated with a more severe form of the disease. It is not known how these mutations affect the severity of PKD when paired with different mutations.

Demographics

PKD is the most common of the hereditary non-spherocytic anemias, with 500 families documented as suffering from the disorder. It occurs worldwide, but most cases have been reported in northern Europe, Japan, and the United States. In general, PKD does not appear to affect one gender more than another or be more common in certain regions. However, there are studies of an Amish group in Pennsylvania where a severe form of PKD is more common. The three mutations found in the *PKLR* gene have been linked to individuals of specific descents. Caucasians of northern and central European descent are more likely to have the *1529A* mutations, individuals of southern European descent usually have the *1456T* mutation, and individuals of Asian descent are more likely to have the *1468T* mutation. The prevalence of PKD in people of European descent is 1 in 20,000.

Signs and symptoms

In general, the more severe the PKD, the earlier in life symptoms tend to be detected. Individuals with the more severe form of PKD often show symptoms soon after birth, but most individuals with PKD begin to exhibit symptoms during infancy or childhood. In individuals with the more mild form of PKD, the condition is sometimes not diagnosed until late adulthood, after an acute illness, or during a pregnancy evaluation.

Symptoms of PKD are similar to those symptoms seen in individuals who have long-term hemolytic anemia. The more common symptoms include variable degrees of jaundice (a yellowish pigment of the skin), slightly to moderately enlarged spleen (splenomegaly), and increased incidence of gallstones. Other physical effects of PKD can include smaller head size and the forehead appearing prominent and rounded (called frontal bossing). If a child with PKD has their spleen removed, their growth tends to improve. Even within the same

KEY TERMS

Anemia—A blood condition in which the level of hemoglobin or the number of red blood cells falls below normal values. Common symptoms include paleness, fatigue, and shortness of breath.

Catalyst—A substance that changes the rate of a chemical reaction but is not physically changed by the process.

Compound heterozygotes—Having two different mutated versions of a gene.

Enzyme—A protein that catalyzes a biochemical reaction or change without changing its own structure or function.

Glycolysis—The pathway in which a cell breaks down glucose into energy.

Hemolytic anemia—Anemia that results from premature destruction and decreased numbers of red blood cells.

Heterozygote—Having two different versions of the same gene.

Homozygote—Having two identical copies of a gene or chromosome.

Isozyme/Isoenzyme—A group of enzymes that perform the same function, but are different from one another in their structure or how they move.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and can be transmitted to offspring.

Nonspherocytic—Literally means not sphere-shaped. Refers to the shape of red blood cells in nonspherocytic hemolytic anemia.

family, individuals can have different symptoms and severity of PKD.

In individuals with PKD, the red blood cells are taken out of their circulation earlier than normal (shorter lifespan). Because of this, individuals with PKD have hemolytic anemia. Additionally, the anemia or other symptoms of PKD may worsen during a sudden illness or pregnancy.

Diagnosis

A diagnosis of PKD can be made by measuring the amount of pyruvate kinase in red blood cells. Individuals with PKD tend to have 5%–25% of the normal amount of pyruvate kinase. Carriers of PKD also can have less

QUESTIONS TO ASK YOUR DOCTOR

- What is the long-term prognosis of pyruvate kinase deficiency?
- What is the likelihood that I may have the same condition as my sibling?
- What kinds of treatments are used to treat pyruvate kinase deficiency?
- Are my children likely to inherit this condition from me?

pyruvate kinase in their red blood cells, approximately 40%–60% of the normal value. However, there is an overlap between the normal range of pyruvate kinase and the ranges seen with carriers of PKD. Therefore, measuring the amount of pyruvate kinase in the red blood cells is not a good method of detecting carriers of PKD. If the mutations causing PKD in a family are known, it may be possible to perform mutation analysis to determine carrier status of an individual and to help diagnose individuals with PKD.

Treatment and management

In the severest cases, individuals with PKD will require multiple blood transfusions. In some of those cases, the spleen may be removed (splenectomy). Red blood cells are normally removed from circulation by the spleen. By removing an individual's spleen (usually a child), the red blood cells are allowed to stay in circulation longer than normal, thereby reducing the severity of the anemia. After a splenectomy, or once an individual with PKD is older, the number of transfusions tends to decrease.

Prognosis

The prognosis of PKD is extremely variable. Early intervention and treatment of symptoms frequently improve the individual's health. Without treatment, individuals may experience severe complications that could become fatal. Individuals with a mild form of PKD may appear to have no symptoms at all.

Race and genetics

Understanding race

Race, based on appearance and sometimes family history, is a highly subjective and socially defined way that cultures classify individuals into groups. For years, many people have mistakenly believed that there is a biological or genetic basis for race and that differences in characteristics such as health, intelligence, and athletic ability are the result of genetic differences. This is simply not true. There are no “biological races”: Racial identity is not contained in the DNA of an individual or group, nor is it explained by any portion of the human genome.

Assigning people to different races does not explain or define human genetic variation. The characteristics and attributes mistakenly ascribed to race are more likely related to a population’s geographic location, which is called “geographic ancestry,” and does relate to genetics but is not the same as race. People who live in the same region are likely to be similar genetically. Genetic variation is related to geographic distance; the farther apart people are from one another, and the longer they have lived far from one another, the more likely they are to have genetic differences. Other differences often attributed to race result from differences in how people live, such as diet and nutrition, physical activity levels, and access to medical care. For people of color many of these differences in lifestyle, such as limited access to healthy food and medical care and living or working in unsafe environments, result from systemic and structural racism, not from any biological or genetic differences.

A brief overview of the history of race

The history of race is inextricably bound to the history of racism. Many historians assert that the concept of race originated as a way to force millions of dark skinned Africans to the Americas between 1525 and 1866. Europeans and later Americans rationalized this action, maligning and debasing their captives and

declaring them inferior based on the color of their skin. To justify this economic exploitation, they developed quasi-scientific explanations of race. Some asserted that dark skin was the result of vapors in the skin or darkened sperm; others claimed that heat and air darkened the skin.

In the mid 1700s, the notion of “degeneration” gained favor. Degeneration proposed that the original, superior race was white and that as this race migrated, climate induced mutations increased the pigment in skin. This notion is the opposite of our current understanding of skin color as the result of natural selection and the adaptation that occurred with each successive migration from Africa.

Early physicians bolstered this racist notion and attempted to develop a scientific rationale for it. They described dark skin as damaged by living in a tropical climate, and European physicians erroneously claimed that Black Africans suffered from a host of physical and mental disabilities such as limited intelligence and laziness. In 1851 Samuel A. Cartwright (1793–1863), a physician who practiced in Mississippi and Louisiana, published a “Report on the Diseases and Physical Peculiarities of the Negro Race” that described a mental illness called drapetomania, which was believed to cause slaves to run away, and dysaesthesia aethiopica, a form of lethargy that supposedly afflicted Africans who were not enslaved or watched over by whites.

European physicians and naturalists persisted in advancing the belief that race was a way to distinguish humans from one another. German physician, naturalist, physiologist, and anthropologist Johann Friedrich Blumenbach (1752–1840) introduced the term “Caucasian” to describe white Europeans because he believed that the “white race” originated in the Caucasus region, which includes parts of Asia and Europe between the Black Sea and the Caspian Sea and is home to Armenia, Azerbaijan, Georgia, and parts of Southern Russia. Unlike many of his naturalist colleagues who contended that Africans were an entirely different species, Blumenbach believed that anatomical variations among humans did not

represent differences between human species; instead he posited that race distinguished subspecies of humans. Based on his detailed studies of skulls and human anatomy, Blumenbach concluded that there were five distinct races of humans: Caucasian, Mongolian, Malayan, Ethiopian, and American. Although he incorrectly described and designated distinct races, he argued strongly against the use of anthropology as a means to promote discrimination.

Although abolitionists and others sought to debunk these racist ideas and spoke out against unscientific racial claims, they nonetheless took hold in the United States, largely because they appeared to support slavery. Many historians and observers feel that these incorrect and discriminatory ideas are deeply rooted in American history and persist in the 21st century. They argue that although the U.S. Civil War formally ended the institution of slavery, it didn't end racism, and the small, slow, uneven progress in ending race-based prejudice and discrimination drags on.

The 1950s and 1960s saw a robust campaign to end racial segregation and discrimination. The August 1963 March on Washington, in which more than 200,000 people of all races gathered in Washington, DC, to advocate for civil rights legislation and job equality is one of the best known events of the civil rights movement. The peaceful demonstration was attended by civil rights leaders and it is where Martin Luther King, Jr. (1929–1968) made his famous and oft-quoted speech, “I Have a Dream.” King and other civil rights leaders witnessed the signing of the Civil Rights Act of 1964, which guaranteed equal employment, limited the use of literacy tests for voters, and enabled federal authorities to ensure that public facilities were integrated.

On March 7, 1965, 600 demonstrators marched in Alabama from Selma to Montgomery to protest the killing of civil rights activist Jimmie Lee Jackson (1938–1965) by a white police officer and express their support for the 15th amendment, which was ratified in 1870 and prohibited the federal and state governments from denying citizens the right to vote based on race, color, or previous condition of servitude. When the peaceful demonstrators approached the Edmund Pettus Bridge, they were blocked from crossing it by state and local police, and as they attempted to cross the bridge they were brutally beaten and teargassed by the police. The events on the bridge were widely televised and became known as “Bloody Sunday.”

Systemic racism persisted in the United States, and in May 2020 efforts to recognize, expose, and eliminate it were reignited after Minnesota police murdered an African American man named George Floyd (1973–

2020) because a store clerk suggested that he may have used a counterfeit \$20 bill to pay for his purchases. Officer Derek Chauvin (1976–), one of four police officers at the scene, knelt on Floyd's neck and back for 9 minutes and 29 seconds as Floyd begged for his life. Chauvin was convicted of second-degree unintentional murder, third-degree murder, and second-degree manslaughter, and was sentenced to 22-and-a-half years in prison. Floyd's murder and previous acts of police brutality and high-profile police killings and racially motivated violence restarted the “Black Lives Matter movement,” which was founded in 2013 to “eradicate white supremacy and build local power to intervene in violence inflicted on Black communities by the state and vigilantes.” The movement prompted many American institutions and individuals to engage in a racial reckoning. Books, broadcasts, speeches, and demonstrations catapulted race to the forefront of Americans' consciousness and corporations pledged billions of dollars to address injustice. Although many remain hopeful that a national reflection on racism might catalyze efforts to overcome systemic injustice, national polls found that by June 2021, interest in, and enthusiasm for, the movement had waned among white Americans.

Genetics and five races

Even as knowledge, appreciation, and enthusiasm for genetics research increased in the 21st century, misperceptions about race persisted. Completion of the Human Genome Project in 2003 enabled scientists and researchers to trace human ancestry using genetics. Consumers also eagerly sought clues to their past in readily accessible, affordable, convenient, at-home genetic testing. These popular tests purport to accurately determine an individual's geographic origins based on a genetic analysis. But these direct-to-consumer tests that estimate ancestral composition are still based on the old, misguided premise that DNA can be used to assign people to one of five distinct races: European, African, Asian, Oceania, or Native American. This antiquated and rigid view of race assumes that each race has a uniform genetic identity and that the variation between races is great.

It is now known that there is no uniform identity, and that genetic variation within a single region is large. It is also true that while human populations do vary based on geographic regions of origin, the genetic variation between different regions is very small. So, while the five races do offer a way to describe the geographic distribution of populations, variation between them is smaller, a scant 0.1%, and blurrier than popular genetic tests suggest.

A 2002 landmark study conducted by Stanford University researchers that considered the genotypes of more

than 1,000 people found that within-population differences among individuals accounted for 93% to 95% of genetic variation, while differences between major groups accounted for just 3% to 5%. The researchers identified six main genetic clusters; five of these corresponded to major geographic regions. They found no evidence that the populations typically termed races have distinct genetic identities, and they found substantial genetic variation within groups termed races. In fact, there is so much variation within races that two people of African descent may be more genetically similar to a European than to one another.

Race is a social construct

Today, most scientists concur that race is a social construct, not a biological characteristic. Humans invented the classification of people into races as a way to distinguish physical differences; there are no genes common to all people who are white, black, or Asian. Even though race has served in the past as a way to characterize human genetic diversity, it is a very weak stand-in for diversity. At best, race is a poorly defined marker of diversity and an inexact stand-in for the relationship between ancestry and genetics. From the standpoint of biology and genetics, it is much more useful to describe populations and individuals based on their ancestry, which is the geographical origins of their predecessors.

Genetic disorders

If race is not related to genetics, then why do some genetic disorders disproportionately affect people from particular racial and ethnic groups? This is because some genetic disorders occur more frequently among people who come from a specific geographic area. People from the same geographic area share certain versions of genes, called gene variants that they have inherited from their ancestors. When one of these gene variants contains a disease-causing mutation, then the disease will occur more frequently in the racial or ethnic group. Advanced genotyping methods are beginning to elucidate patterns for genetic diseases and disorders within specific populations; these patterns are increasingly described according to their biogeographical ancestry rather than according to race.

Examples of genetic disorders that appear more frequently in particular racial or ethnic groups include sickle cell disease, which is more common in people of African, African American, or Mediterranean heritage; and Tay-Sachs disease, which occurs more frequently among Jewish people with eastern and central European heritage and people with French Canadian ancestry. Other genetic

disorders such as cystic fibrosis primarily affect white people.

Health disparities

Other diseases that are not strictly considered genetic disorders, even though specific genetic variants may increase susceptibility or risk of developing these conditions, disproportionately affect African-Americans. These include:

- **Asthma.** African Americans are three times as likely as white Americans to die from asthma.
- **Cancer.** African American men are 40% more likely to die from cancer than their white peers and African American women are 20% more likely to die than white women. African American men are 50% more likely than white men to develop lung cancer, even though they have less exposure to tobacco.
- **Diabetes.** African Americans suffer from diabetes 60% more than do white Americans and are much more likely to suffer the consequences of untreated or inadequately treated diabetes.
- **Hypertension (high blood pressure).** African Americans develop hypertension more frequently and at younger ages than do whites. More than 40% of African Americans age 20 and older have hypertension, which is a risk factor for heart disease and stroke.
- **Stroke.** African Americans have nearly twice the risk of first stroke than do whites and strokes claim the lives of four times as many African Americans ages 35 to 54 compared to whites.
- **Sarcoidosis,** an inflammatory disease that affects many organs, but mostly scars the lungs, occurs 16 times more frequently among African Americans than whites.

Although these and other conditions disproportionately affect African Americans, it is not because of their race. Race is a proxy for other structural barriers to health including socioeconomic status, which not only affects lifestyle issues related to health—such as diet and nutrition, physical activity, safe housing and workplaces, and stable employment—but also access to quality medical care. Access to health care is a key determinant of health and even people of color with access to health-care services may find those services mired in institutionalized racism. The concerns of African American patients may not be taken seriously, their complaints may be dismissed, and they may be diagnosed later, when treatment may be less effective.

Health equity in genetic testing

In addition to health disparities resulting from racism and income inequality, medical research has failed to

KEY TERMS

Phenotype—An individual's observable traits, such as height, eye color, and blood type. The genetic contribution to the phenotype is called the genotype. Some traits are largely determined by the genotype, while other traits are largely determined by environmental factors.

Racial disparities—Inequities and inconsistencies in the way people are treated based on the color of their skin, in terms of socioeconomic status, education, access to health care, housing, and other aspects of life.

Social determinants of health—Conditions in the places where people live, learn, work, and play that affect a wide range of health and quality-of-life issue for individuals and groups.

Systemic racism—Also known as institutional racism, this is racism written into the laws, regulations, and practices of institutions, organizations, and groups. Systemic racism results in discrimination in education, housing, employment, health care, the criminal justice system and other aspects of life.

include diverse populations. This inequity is especially glaring in genetics research; most data are collected from white study subjects rather than diverse populations. Further, in 2021, some published genetics research still identified racial categories as biological variables. By overlooking and omitting information from diverse populations, some researchers, physicians, and public health professionals are ill-equipped to meet the needs of diverse populations and populations that are disproportionately underserved.

Polygenic risk scores, which estimate the effect of multiple genetic variants on a person's phenotype, are an example of a technology designed to improve risk management and treatment of people with heart disease, cancer, and diabetes—diseases that disproportionately affect people of color. But the majority of data used to develop these risk scores were obtained from whites of European ancestry; they do not reflect the patients of color who, in many cases, stand to benefit most from them.

Today, clinical genetic testing is still inadequate because it does not include or address the majority of the world's population, which is of non-European ancestry. It remains a challenge for all health-care systems to reduce inequities and to offer all populations the

opportunity to obtain accurate genetic information to inform their medical decision-making, enabling clinicians and researchers to meet the health-care needs of all people.

Raynaud's disease

Definition

Raynaud's disease is a disorder in which the fingers or toes (digits) suddenly experience decreased blood circulation. It is characterized by repeated episodes of color changes of the skin of digits during cold exposure or emotional stress.

Description

Raynaud's disease can be classified as one of two types: primary (or idiopathic) and secondary (also called Raynaud's phenomenon). Primary Raynaud's disease has no predisposing factor, is milder, and causes fewer complications. About half of all cases of Raynaud's disease are of this type. Women are seven times more likely than men to develop primary Raynaud's disease. The average age of diagnosis is between 20 and 40 years. Approximately 3 out of 10 people with primary Raynaud's disease eventually progress to secondary Raynaud's disease after diagnosis. About 15% of individuals improve.

Secondary Raynaud's disease is the same as primary Raynaud's disease but occurs in individuals with a predisposing factor, usually a form of collagen vascular disease. What is typically identified as primary Raynaud's may be later identified as secondary once a predisposing disease is diagnosed. This occurs in approximately 30% of patients. As a result of the predisposing disease, the secondary type is often more complicated and severe, and is more likely to worsen.

Several related conditions that predispose persons to secondary Raynaud's disease include scleroderma, lupus erythematosus, rheumatoid arthritis, and polymyositis. Pulmonary hypertension and some nervous system disorders such as herniated discs and tumors within the spinal column, strokes, and polio can progress to Raynaud's disease. Finally, injuries due to mechanical trauma caused by vibration (such as that associated with chain saws and jackhammers), repetitive motion (carpal tunnel syndrome), electrical shock, and exposure to extreme cold

can lead to the development of Raynaud's disease. Some drugs used to control high blood pressure or migraine headaches have been known to cause Raynaud's disease.

Genetic profile

There is significant familial aggregation of primary Raynaud's disease. However, no causative gene had been identified.

Risk factors for Raynaud's disease differ between males and females. Age and smoking seem to be associated with the disease only in men, while the associations of marital status and alcohol use with Raynaud's disease are usually only observed in women. These findings suggest that different mechanisms influence the expression of Raynaud's disease in men and women.

Demographics

The prevalence of Raynaud's phenomena in the general population varies from 4%–15%. Females are seven times more likely to develop Raynaud's diseases than are men. The problem has not been correlated with coffee consumption, dietary habits, occupational history (excepting exposure to vibration), or exposure to most drugs. An association between Raynaud's disease and migraine headaches has been reported. Secondary Raynaud's disease is common among individuals with systemic lupus erythematosus in tropical countries.

Signs and symptoms

Both primary and secondary Raynaud's disease signs and symptoms are thought to be due to arterioles overreacting to stimuli. Cold normally causes the tiny muscles in the walls of arteries to contract, thus reducing the amount of blood that can flow through them. In people

A woman's hands affected by Raynaud's disease, where blood flow is being restricted to the fingers. (Graham Dunn/Alamy)

Raynaud's Disease: pedigree analysis chart (Gale)

with Raynaud's disease, the extent of constriction is extreme, thus severely restricting blood flow. Attacks or their effects may be brought on or worsened by anxiety or emotional distress.

There are three distinct phases to an episode of Raynaud's disease. When first exposed to cold, small arteries respond with intense contractions (vasoconstriction). The affected fingers or toes (in rare instances, the tip of the nose or tongue) become pale and white because they are deprived of blood and, thus, oxygen. In response, capillaries and veins expand (dilate). Because these vessels are carrying deoxygenated blood, the affected area then becomes blue in color. The area often feels cold and tingly, or numb. After the area begins to warm up, the arteries dilate. Blood flow is significantly increased. This changes the color of the area to a bright red. During this phase, persons often describe the affected area as feeling warm and throbbing painfully.

Raynaud's disease may initially affect only the tips of fingers or toes. As the disease progresses, it may eventually involve all of one or two digits. Ultimately, all the fingers or toes may be affected. About 1 person in 10 will experience a complication called sclerodactyly. In sclerodactyly, the skin over the involved digits becomes tight, white, thick, smooth, and shiny. In approximately 1% of cases of Raynaud's disease, deep sores (ulcers) may

develop in the skin. In rare cases of frequent, repetitive bouts of severe ischemia (decreased supply of oxygenated blood to tissues or organs), tissue loss, or gangrene, may result and amputation may be required.

Diagnosis

Primary Raynaud's disease is diagnosed following the four components of the Allen-Brown criteria. The certainty of the diagnosis and severity of the disease increase as more criteria are met. The first is that at least two of the three color changes must occur during attacks provoked by cold and/or stress. The second is that episodes must occur periodically for at least two years. The third is that attacks must occur in both the hands and the feet in the absence of vascular occlusive disease. The last is that there is no other identifiable cause for the Raynaud's episodes.

A cold stimulation test may also be performed to help to confirm a diagnosis of Raynaud's disease. The temperature of affected fingers or toes is taken. The hand or foot is then placed completely into a container of ice water for 20 seconds. After removal from the water, the temperature of the affected digits is immediately recorded. The temperature is taken every 5 minutes until it returns to the pre-immersion level. Most individuals recover normal temperature within 15 minutes. People

KEY TERMS

Arteriole—The smallest type of artery.

Artery—A blood vessel that carries blood away from the heart to peripheral tissues.

Gangrene—Death of a tissue, usually caused by insufficient blood supply and followed by bacterial infection of the tissue.

Idiopathic—Of unknown origin.

Lupus erythematosus—A chronic inflammatory disease that affects many tissues and parts of the body including the skin.

Polymyositis—An inflammation of many muscles.

Pulmonary hypertension—A severe form of high blood pressure caused by diseased arteries in the lung.

Rheumatoid arthritis—A chronic autoimmune disease marked by inflammation of the membranes surrounding joints.

Scleroderma—A relatively rare autoimmune disease affecting blood vessels and connective tissue that makes skin appear thickened.

with Raynaud's disease may require 20 minutes or more to reach their pre-immersion temperature.

Laboratory testing is performed frequently. However, these results are often inconclusive for several reasons. Provocative testing such as the ice immersion just described is difficult to interpret because there is considerable overlap between normal and abnormal results. The antinuclear antibody test of blood is usually negative in Raynaud's disease. Capillary beds under fingernails usually appear normal. Erythrocyte sedimentation rates are often abnormal in people with connective tissue diseases. Unfortunately, this finding is not consistent in people with Raynaud's disease.

Treatment and management

There is no known way to prevent the development of Raynaud's disease. Furthermore, there is no known cure for this condition. Therefore, avoidance of the trigger is the best supportive management available. Most cases of primary Raynaud's disease can be controlled with proper medical care and avoidance.

Many people are able to find relief by simply adjusting their lifestyles. Affected individuals need to stay warm and keep their hands and feet well covered in cold weather. Layered clothing, scarves, heavy coats, heavy

socks, and mittens over gloves are suggested because gloves alone allow heat to escape. It is also recommended that patients cover or close the space between their sleeves and mittens. Indoors, they should wear socks and comfortable shoes. Excessive emotional stress should be avoided. Smokers should quit, as nicotine worsens the problem. The use of vibrating tools should be avoided as well.

Biofeedback has been used with some success in treating primary Raynaud's. This involves teaching people to "think" their fingers and toes to be warm by willing blood to flow through affected arterioles. A patient is given continuous information on the temperature of his or her digits and then taught to voluntarily control this temperature. Biofeedback has had only limited success. Occasionally, medications such as calcium-channel blockers, reserpine, or nitroglycerin may be prescribed to relax artery walls and improve blood flow.

Because episodes of Raynaud's disease have also been associated with stress and emotional upset, the condition may be improved by learning to manage stress. Regular exercise is known to decrease stress and lower anxiety. Hypnosis, relaxation techniques, and visualization are also useful methods to help control emotions.

Some alternative practitioners believe that certain dietary supplements and herbs may be helpful in decreasing the vessel spasm of Raynaud's disease. Suggested supplements include vitamin E (found in fruits, vegetables, seeds, and nuts), magnesium (found in seeds, nuts, fish, beans, and dark green vegetables), and fish oils. The circulatory herbs cayenne, ginger, and prickly ash may help enhance circulation to affected areas.

Prognosis

The prognosis for most people with Raynaud's disease is very good. In general, primary Raynaud's disease has the best prognosis, with a relatively small chance (1%) of serious complications. Approximately half of all affected individuals do well by taking simple precautions and never require medication. The prognosis for people with secondary Raynaud's disease (or phenomenon) is less predictable. This prognosis depends greatly on the severity of other associated conditions such as scleroderma, lupus, or Sjögren's syndrome. A long-term case study of over 30 years concluded in 2015 that among Caucasians with a diagnosis of Raynaud's phenomenon there was a high correlation with cardiovascular disease and cardiovascular-related death. This study went on to hypothesize that Raynaud's phenomenon may be an indicator of a more serious underlying vascular disease, which is important to note for management of the condition.

QUESTIONS TO ASK YOUR DOCTOR

- How do the two types of Raynaud's disease differ from each other?
- What are the most serious medical complications associated with Raynaud's disease?
- How is Raynaud's disease diagnosed?
- What support groups or nonprofit organizations can provide me with additional information about Raynaud's disease?
- How often should I be screened for other autoimmune or vascular diseases?

Recurrence risk counseling

Definition

Recurrence risk is a statistic estimating the chance that a genetic disorder that has appeared in one or more members of a family will reappear in the present or future generations. It can be expressed as a probability (a proportion between 0 and 1, with 0 indicating that an event cannot occur, and 1 indicating that it must occur); as a percentage; as odds; or as chance. For example, if a genetic disorder has a probability of 0.5 recurrence in a family, it is equally likely to recur or not recur. The same probability can be expressed as a 50% likelihood, or as 1 chance in 2 that the disorder will recur in the family.

Recurrence risk counseling is therefore a specialized form of genetic counseling that requires numerical calculations to estimate the probability of recurrence following the collection of information from the family and obtaining a diagnosis of the specific genetic disorder. While such calculations are relatively straightforward when Mendelian or single-gene disorders affecting one set of parents and their immediate children are involved, they can become extremely complex when the genetic disorder in question does not follow Mendelian patterns of inheritance or when second- or third-degree relatives are brought into the discussion.

Purpose

Recurrence risk counseling has several goals:

- Gathering information about the family of the proband (i.e., the person who is being evaluated for the presence of a genetic disorder or the risk of developing one). Other members of a family may have the disorder in question, but the person who seeks medical attention for the disorder is designated the proband.
- Establishing the correct diagnosis of the genetic disorder in question. In the past, genetic testing was most often done for one gene at a time. More recently, multigene or panel testing has become widely available. Last, a growing number of people have taken direct-to-consumer (DTC) genetic tests, which require confirmation by a clinical

laboratory. Whichever test was used, accurate identification of the genetic disorder is essential to recurrence risk counseling.

- Building rapport with the proband and his or her family. People vary widely in their ability to understand medical information and their ability to cope with the emotional stress aroused by finding out that a genetic disorder runs in one's family. Recurrence risk counseling requires an ability to convey genetic information in nontechnical language, patience, and a willingness to repeat or reword the information as often as needed.
- Offering ongoing support to the family. Recurrence risk counseling is nondirective in that the proband and other family members are not told what to do with the information provided to them but are encouraged to learn about their options and discuss the implications and possible outcomes of these options among themselves.

Description

Recurrence risk counseling for any genetic disorder begins with the construction of a pedigree, which is a visual chart of the proband's family. The pedigree begins with the proband, whose sex is indicated by a circle if female, or a square if male. The parents are then added, siblings (if any) in order of birth (beginning with the oldest at left and moving rightward with younger siblings), then uncles, aunts, grandparents, and cousins. Those who have died are identified with a diagonal line through their circle or square, with age at death and cause of death noted. Relatives whose sex is unknown are represented by a diamond.

Generations are numbered with Roman numerals, with I for the oldest generation on the chart. The pedigree should include ethnic identifications and as many relatives unaffected by the disorder as possible. Each specific person on the pedigree is identified with their generation number, any diagnoses received along with age at onset, current age if known, and an asterisk indicating whether they are willing to participate in the study. Examples of pedigree constructions can be found throughout this book, and for more information on the subject, please see the entry on "Pedigree analysis."

Mendelian disorders

Mendelian (single-gene) disorders are the simplest to calculate risk recurrence, because they follow the basic rules of inheritance discovered by the German botanist Gregor Mendel (1822–1884) in the mid-nineteenth century. In many cases, the risk can be illustrated by using a Punnett square, which is a grid that predicts the probability of an offspring having a particular genotype when maternal alleles for a single trait are crossed with

paternal alleles. Capital letters are used for dominant alleles, and lowercase letters for recessive alleles. For example, brown eye color is dominant (B) in humans, and blue eye color is a recessive trait (b). If two parents who are heterozygous for brown eyes have a child, a Punnett square will show that the child has a 25% chance of being homozygous for brown eyes (BB); a 50% chance of being heterozygous for brown eyes (Bb); and a 25% chance of having blue eyes (bb).

AUTOSOMAL DOMINANT. An autosomal dominant disorder is one in which one altered copy of a gene is sufficient for a single-gene disorder to appear in the offspring. Autosomal dominant disorders can affect either sex, and they can be transmitted from father to son. The pathogenic variant (disease-causing mutation) may be inherited from either parent, or it may be a new mutation. Examples of autosomal dominant disorders include Marfan syndrome, polycystic kidney syndrome, myotonic muscular dystrophy, and Huntington's disease.

AUTOSOMAL RECESSIVE. An autosomal recessive disorder is one in which a person must have inherited two copies of the variant gene, one from each parent. The parents typically do not show any signs of the disorder, and the disorder often skips generations in an affected family. Examples of autosomal recessive disorders include cystic fibrosis, sickle cell disease, and phenylketonuria.

X-LINKED DOMINANT. X-linked disorders are those caused by variant genes on the X chromosome, one of two sex chromosomes. A dominant variant gene on the X chromosome will cause the disorder in male offspring (who have only one X chromosome) and in female offspring (who have two X chromosomes). However, females typically have less severe symptoms than males. In addition, fathers cannot pass x-linked disorders to their sons. Aicardi syndrome is an example of an X-linked dominant disorder.

X-LINKED RECESSIVE. X-linked recessive disorders are also caused by variant genes on the X chromosome. In males, who have only one X chromosome, one variant recessive gene is sufficient to cause the disorder. Females must inherit the variant gene from both parents to have the disorder. Because the likelihood of inheriting two copies of the variant gene is relatively small, X-linked recessive disorders appear much more often in males than in females. Females are, however, likely to be carriers of the variant gene. Examples of X-linked recessive disorders include hemophilia A and Duchenne muscular dystrophy.

Y-LINKED. Y-linked genetic disorders are caused by variant genes on the Y chromosome, which are present only in males. Y-linked disorders can only be passed from father to son. Most of these disorders are rare but usually result in reduced fertility.

KEY TERMS

Allele—One of two (or more) forms of the same gene at the same place on a chromosome.

Autosome—Any chromosome that is not a sex chromosome. The human genome has 22 pairs of autosomes.

Bayes' theorem—A theorem that estimates the probability of an event, based on knowledge of prior conditions that may be related to the event. It is named for Thomas Bayes (c. 1701–1761), an English Presbyterian minister and Fellow of the Royal Society. Bayes' theorem is used in genetic risk assessment for non-Mendelian disorders.

Carrier—In genetics, a person who has a genetic mutation associated with a disease and is capable of passing it on. A carrier may or may not display the symptoms of the disease.

Cascade testing—A term that refers to performing genetic counseling and testing in blood relatives of a person identified as having a specific genetic mutation. It is most commonly recommended for the relatives of patients carrying a genetic mutation linked to cancer.

Empirical—Relying on, or derived from, observations gained through the senses or by experimentation.

Genotype—The complete set of an organism's genetic material. The term is sometimes used to refer to the genes or set of genes for a single trait, such as height or eye color.

Heterozygous—Referring to the genetic condition of having inherited two different forms (alleles) of a particular gene from each of a person's two parents.

Homozygous—Referring to genetic condition of having inherited the same allele for a specific gene from both parents.

Imprinting—A condition in which the expression of a gene depends upon the sex of the parent who passed on the gene to the child.

Klinefelter syndrome—A genetic disorder characterized by one or more extra X chromosomes in a male, with a 47,XXY, 48,XXX, or 49,XXXXY karyotype. Most men with this syndrome are infertile or have reduced fertility. The syndrome is named for Harry Klinefelter (1912–1990), an American endocrinologist who first described it in 1942.

Mendelian disease—A disease caused by a single mutated gene; also called a single-gene disease. These diseases are named for Gregor Mendel (1822–1884), an Austrian monk who discovered the basic

Non-Mendelian inheritance patterns

Non-Mendelian genetic disorders do not follow the inheritance patterns outlined by Mendel for single-gene disorders. They may have one or more of the following characteristics:

- **Codominance.** In codominant inheritance, both alleles for a trait are equally expressed in the phenotype of the offspring. In humans, the most common example of codominance is the A and B blood types; a person who inherits the A allele from one parent and the B allele from the other will have AB type blood. (Type O is recessive to both A and B.)
- **Reduced penetrance.** Penetrance refers to the proportion of people with a variant gene who exhibit the symptoms of a genetic disorder. If there are people with the variant who do not develop such symptoms, the disorder is said to have reduced penetrance. Many familial cancer syndromes, including those associated with mutations in the *BRCA1* and *BRCA2* genes, have reduced penetrance. This characteristic complicates risk-assessment counseling for these disorders.
- **Variable expressivity.** Variable expressivity is a term that refers to differences in the type and severity of symptoms that appear in persons with the disorder in question. For example, some people with Marfan syndrome have very long fingers and are unusually tall but are otherwise healthy, while others have life-threatening cardiovascular complications.
- **Imprinting.** Imprinting is seen in genetic disorders in which the expression of a gene depends on the sex of the parent who contributed it to the offspring. The best-known example in humans concerns a chromosome deletion at 15q11-13. If the deletion occurs on the copy of the chromosome inherited from the father, the child will develop Prader-Willi syndrome; if it occurs on the copy inherited from the mother, the child will develop Angelman syndrome.
- **Mitochondrial disorders.** Mitochondrial disorders are a group of disorders caused by mutations in either mitochondrial DNA or in the genes in the cell nucleus that code for mitochondria. Mitochondrial DNA (mtDNA) is inherited only from the mother; however,

principles of inheritance of single-gene traits through experimentation with plants in his garden.

Mitochondria (singular, mitochondrion)—Organelles in the cytoplasm of cells that contain genetic material and enzymes responsible for converting food to usable energy.

Mitochondrial disease—Any of several hundred inherited conditions caused by functional failure of the mitochondria within cells.

Monogenic disease—Another term for a single-gene disorder.

Mosaicism—A condition in which two or more genetically different sets of cells occur in the same individual.

Multifactorial disorders—A general term for polygenic disorders complicated by the effects of environmental factors. Multifactorial disorders do not have clear patterns of inheritance. They are sometimes called complex diseases or disorders.

Pedigree—A genetic diagram of a family tree that shows the appearance of a trait or disorder across several generations.

Penetrance—The frequency with which the characteristics transmitted by a gene appear in individuals possessing that gene. In medical genetics, the

penetrance of a disease-causing mutation is the proportion of persons with the mutation who display clinical symptoms of the disease.

Phenotype—The set of observable characteristics or traits of an organism. It includes physical form and structure, development, metabolic processes, movement, and behavior.

Polygenic—Referring to an inherited disorder or trait whose phenotype is influenced by more than one gene.

Proband—The specific person being reported on in a genetic investigation. In most cases, the proband is the first member of a family to bring the disorder to medical attention.

Punnett square—A grid used to determine the probability that the offspring of two parents with a single-gene trait being crossed will have a particular genotype. The square is named for Reginald Punnett, a British geneticist who first devised it in 1905.

Turner syndrome—A chromosomal disorder with a 45,X or 45,X0 karyotype that affects only females, in which one of the X chromosomes is either partially or completely missing. Most women with Turner syndrome are infertile because of a lack of ovarian function.

both males and females can develop mitochondrial disorders. In addition, the 37 genes in human mitochondrial DNA show new mutations more frequently than the genes in the cell nucleus.

- **Polygenic inheritance.** Many human characteristics are determined by a combination of a number of different genes, such as height, intelligence, and skin color. Many disorders are polygenic as well, including autism spectrum disorders, hypertension, diabetes, and coronary heart disease. In a polygenic disorder, each variant gene contributes a small additive effect to the eventual outcome.
- **Multifactorial disorders.** Multifactorial disorders are those that represent interactions between a person's heredity and his or her environment, which includes such factors as nutrition, climate, sun exposure, and personal behaviors like smoking, heavy drinking, or drug consumption. Multifactorial disorders are sometimes called complex disorders. These have a tendency to run in families but at much lower levels than single-gene disorders that follow Mendelian patterns of inheritance.

The likelihood that a given individual will exhibit the phenotype of a multifactorial disorder depends on the number of genes that contribute to the disorder plus exposure to the environmental factors that favor the emergence of the disorder. Only individuals with enough multiple genes who are in the presence of certain environmental factors will exhibit the phenotype. The threshold is the point at which these factors combine sufficiently for affected individuals to exhibit the phenotype.

- **Disorders with delayed age of onset.** Genetic disorders whose symptoms do not appear until adult life are among the most difficult for assessing the risk of recurrence in a family. For example, in Huntington's disease, symptoms might not appear before age 30, and sometimes not until age 50.
- **Mosaicism.** Mosaicism is a condition in which a person has more than one genetic line of cells as a result of a mutation. It can be found in some women with Turner syndrome and some men with Klinefelter syndrome.

QUESTIONS TO ASK YOUR DOCTOR

- Have you ever referred a patient for recurrence risk genetic counseling?
- Have you ever attempted recurrence risk counseling yourself?
- What is your opinion of the increasing use of Bayes' theorem in genetic risk assessment?
- Have you ever recommended cascade testing to a patient with a hereditary cancer syndrome?

Calculating recurrence risk in non-Mendelian disorders

DATA COLLECTION AND EMPIRICAL OBSERVATIONS.

Calculating recurrence risk for non-Mendelian disorders is usually done by using a combination of data from population studies and empirical observations. The most widely used database for identifying the frequency of a disease-causing gene variation worldwide is the Frequency of Inherited Disorders Database or FINDbase, which was started by a group of Greek researchers in 2006 and has been updated several times since. Empirical observations about recurrence include the following:

- Recurrence risk is higher in first-degree relationships (parents, children, siblings), because these relatives share 50% of their genetic material, compared to 25% for second-degree relatives (grandparents, aunts, uncles, nieces, and nephews) and 12.5% for third-degree relatives (first cousins). The recurrence risk to first-degree relatives of the proband is the square root of the general population risk.
- If the genetic defect is more common in one sex than in the other, the recurrence risk is higher if the proband belongs to the less commonly affected sex.
- Recurrence risk is higher when the proband is more severely affected. For example, if the proband has a bilateral cleft lip and palate, a future sibling has a recurrence risk of 6%. If the cleft lip is on one side only, that risk for a future sibling drops to 2%.
- Recurrence risk is higher if more than one child in the family has already been diagnosed with the genetic disorder in question.
- In hereditary cancer syndromes, the recurrence risk is higher if the proband developed cancer at an unusually early age, if the proband developed more than one type of primary cancer, if there is a cluster of the same type of cancer in close relatives (mother, daughter, and sisters), if the proband has a rare type of cancer (male breast

cancer), or if the proband belongs to an ethnic group known to be at high risk of hereditary cancers. Many genetic counselors recommend cascade testing in hereditary cancer syndromes.

BAYES' THEOREM. Bayes' theorem is a theorem used to calculate probabilities in genetic risk assessments, including risk recurrence. The initial probability of each event is known as its prior probability and is based on anterior family information contained in the pedigree. The observations that modify these prior probabilities allow the geneticist to determine conditional probabilities. In genetic counseling, these observations are usually based on numbers of offspring and/or the results of genetic tests. This type of information is posterior information. The resulting probability for each event or outcome is known as its joint probability. The final probability for each event is known as its posterior or relative probability and is obtained by dividing the joint probability for that event by the sum of all the joint probabilities.

Refsum disease

Definition

Refsum disease is an inherited disorder in which the enzyme responsible for processing phytanic acid is defective. Accumulation of phytanic acid in the tissues and the blood leads to damage of the brain, nerves, eyes, skin, and bones.

Description

Refsum disease was first characterized by the Norwegian physician Sigvald Refsum in the 1940s and is known by other names, such as classical Refsum disease, adult Refsum disease, phytanic acid alpha-hydroxylase deficiency, phytanic acid storage disease, hypertrophic neuropathy of Refsum, hereditary ataxia polyneuritis, and hereditary motor and sensory neuropathy IV. Refsum disease should not be confused with infantile Refsum disease, which was once thought to be a variant of the disorder but is now known to be a genetically and biochemically distinct entity. Sometimes infantile Refsum disease is simply referred to as “Refsum disease,” furthering the confusion.

Living bodies are made up of millions of individual cells that are specifically adapted to carry out particular functions. Within cells are even smaller structures, called organelles, that perform jobs and enable the cell to serve its ultimate purpose. One type of organelle is the peroxisome, whose main function is to break down waste materials or to process materials that, if allowed to accumulate, would prove toxic to the cells.

Phytanic acid is a substance found in foods, such as dairy products, beef, lamb, and some fish. Normally, phytanic acid is processed by a set of enzymes within the cell to convert it to another form. In the past, scientists were unsure where in the cell this process took place, hypothesizing that it may occur in the peroxisome or another

organelle, called the mitochondrion. However, recent research has definitively determined that the enzymes responsible for processing phytanic acid are located in the peroxisome.

Refsum disease is an inherited disorder in which one of the peroxisomal enzymes, phytanic acid hydroxylase (also called phytanic acid oxidase, or phytanyl CoA hydroxylase), is defective, resulting in unprocessed phytanic acid. Consequently, high levels of phytanic acid build up in the tissues of the body and the bloodstream, causing damage to different organ systems.

Genetic profile

Refsum disease is a genetic condition and can be inherited or passed on in a family. The genetic defect for the disorder is inherited as an autosomal recessive trait, meaning that two abnormal genes are needed to display the disease. A person who carries one abnormal gene does not display the disease and is called a carrier. A carrier has a 50% chance of transmitting the gene to his or her children. A child must inherit the same abnormal gene from each parent to display the disease.

Refsum disease is caused by a deficiency in an enzyme, phytanic acid hydroxylase. The gene encoding for this enzyme, called *PAHX* or *PHYH*, was identified in 1997 and mapped to human chromosome 10 (locus: 10pter-p11.2). Several common mutations have been identified in the gene that result in Refsum disease.

Demographics

Refsum disease is rare, but the exact incidence and prevalence of the disorder in the general population is not known. Refsum disease may not be distributed equally among geographical areas or different ethnic groups, as most of the diagnosed cases have been found in children and young adults of Scandinavian heritage.

Signs and symptoms

Patients with Refsum disease generally do not show obvious defects at birth, and growth and development initially appears normal. The onset of clinical symptoms varies from early childhood to age 50, but symptoms usually appear before 20 years of age. The manifestations of Refsum disease primarily involve the nervous system, the eye, the skin, the bones, and, in rare cases, the heart and kidneys.

Phytanic acid deposits in the fatty sheaths surrounding nerves, causing damage and resulting in peripheral neuropathy in 90% of patients with Refsum disease. “Peripheral neuropathy” is the term for dysfunction of the nerves outside of the spinal cord, causing loss of

KEY TERMS

Autosomal recessive—A pattern of genetic inheritance where two abnormal genes are needed to display the trait or disease.

Carrier—A person who possesses a gene for an abnormal trait without showing signs of the disorder. The person may pass the abnormal gene on to offspring.

Cerebellar ataxia—Unsteadiness and lack of coordination caused by a progressive degeneration of the part of the brain known as the cerebellum.

Enzyme—A protein that catalyzes a biochemical reaction or change without changing its own structure or function.

Ichthyosis—Rough, dry, scaly skin that forms as a result of a defect in skin formation.

Mutant—A change in the genetic material that may alter a trait or characteristic of an individual or manifest as disease.

Organelle—Small, subcellular structures that carry out different functions necessary for cellular survival and proper cellular functioning.

Peripheral neuropathy—Any disease of the nerves outside of the spinal cord, usually resulting in weakness and/or numbness.

Peroxisome—A cellular organelle containing different enzymes responsible for the breakdown of waste or other products.

Phytanic acid—A substance found in various foods that, if allowed to accumulate, is toxic to various tissues. It is metabolized in the peroxisome by phytanic acid hydroxylase.

Phytanic acid hydroxylase—A peroxisomal enzyme responsible for processing phytanic acid. It is defective in Refsum disease.

Plasmapheresis—A procedure in which the fluid component of blood is removed from the bloodstream and sometimes replaced with other fluids or plasma.

Retinitis pigmentosa—Progressive deterioration of the retina, often leading to vision loss and blindness.

sensation, muscle weakness, pain, and loss of reflexes. Nerves leading to the nose and ears can also be affected, resulting in anosmia (loss of the sense of smell) in 35% of patients and hearing loss or deafness in 50% of patients. Finally, Refsum disease results in cerebellar

ataxia in 75% of patients. Cerebellar ataxia is a defect in a specific part of the brain (the cerebellum), resulting in loss of coordination and unsteadiness. In contrast to infantile Refsum disease, people with Refsum disease do not show intellectual disability and generally have normal intelligence.

Accumulation of phytanic acid also results in disorders of the eye. The most common finding is retinitis pigmentosa, a degeneration of the retina resulting in poor nighttime vision and sometimes blindness. Disorders of pupil movement and nystagmus (uncontrollable movements of the eye) may also be present due to related nervous system damage. Other eye manifestations of Refsum disease may include glaucoma (abnormally high pressure in the eye, leading to vision loss) and cataracts (clouding of the lens of the eye).

People with Refsum disease often develop dry, rough, scaly skin. These skin changes, called ichthyosis, can occur over the entire body, but sometimes will appear only on the palms and soles of the feet. In addition to these skin abnormalities, 60% of affected people may experience abnormal bone growth, manifesting as shortened limbs or fingers, or abnormal curvatures of the spine.

Patients with Refsum disease usually first present to a physician complaining of weakness in the arms and legs, physical unsteadiness, and/or night blindness or failing vision. The symptoms associated with Refsum disease are progressive and, if untreated, will become more numerous and severe as the patient ages. For reasons that are not completely understood, clinical deterioration can sometimes be interrupted by periods of good health without symptoms.

Diagnosis

Refsum disease is diagnosed through a combination of consistent medical history, physical exam findings, and laboratory and genetic testing. When patients with Refsum disease present to their physicians complaining of visual problems or muscle weakness, physical signs of retinitis pigmentosa, peripheral neuropathy, cerebellar ataxia, or skin and bone changes (as discussed above) are often noted. These findings raise suspicion for a genetic syndrome or metabolic disorder, and further tests are conducted.

Laboratory tests reveal several abnormalities. Normally, phytanic acid levels are essentially undetectable in the plasma. Thus, the presence of high levels of phytanic acid in the bloodstream is highly indicative of Refsum disease. If necessary, a small portion of the patient's connective tissue can be sampled and grown in a laboratory and tested to demonstrate a failure to

QUESTIONS TO ASK YOUR DOCTOR

- What is the role of phytanic acid in Refsum disease?
- What treatments are available to control the progress of Refsum disease?
- How does a physician determine the prognosis for a child with Refsum disease?
- Can you recommend a website that will provide additional information on Refsum disease?

process phytanic acid appropriately. Other associated laboratory abnormalities include the presence of high amounts of protein in the fluid that bathes the spinal cord, or abnormal electrical responses recorded from the brain, muscles, heart, ears, retina, and various nerves as a result of nervous system damage.

Genetic testing can also be performed. When a diagnosis of Refsum disease is made in a child, genetic testing of the *PAHX/PHYH* gene can be offered to determine if a specific gene change can be identified. If a specific change is identified, carrier testing can be offered to relatives. In families where the parents have been identified to be carriers of the abnormal gene, diagnosis of Refsum disease before birth is possible. Prenatal diagnosis is performed on cells obtained by amniocentesis (withdrawal of the fluid surrounding a fetus in the womb using a needle) at about 16–18 weeks of pregnancy or from the chorionic villi (a part of the placenta) at 10–12 weeks of pregnancy.

Treatment and management

There is no cure for Refsum disease, thus treatment focuses on reducing levels of phytanic acid in the bloodstream to prevent the progression of tissue damage. Phytanic acid is not made in the human body and comes exclusively from the diet. Restriction of phytanic acid-containing foods can slow progress of the disease or reverse some of the symptoms. Patients are advised to maintain consumption of phytanic acid below 10 mg/day (the normal intake is approximately 100 mg/day). Sources of high levels of phytanic acid to be avoided include meats (beef, lamb, goat), dairy products (cream, milk, butter, cheese), and some fish (tuna, cod, haddock). Plasma levels of phytanic acid can be monitored periodically by a physician to investigate the effectiveness of the restricted diet and determine if changes are required. As a result of dietary restriction, nutritional deficiencies may

result. Consultation with a nutritionist is recommended to ensure proper amounts of calories, protein, and vitamins are obtained through the diet, and nutritional supplements may be required.

Because phytanic acid is stored in fat deposits within the body, it is important for patients with Refsum disease to have regular eating patterns; with even brief periods of fasting, fat stores are converted to energy, resulting in the release of stored phytanic acid into the blood stream. Thus, unless a patient assumes a regular eating pattern, repeated and periodic liberation of phytanic acid stores results in greater tissue damage and symptom development. For these same reasons, intentional weight loss through calorie-restricted diets or vigorous exercise is discouraged.

Another useful adjunct to dietary treatment is plasmapheresis. Plasmapheresis is a procedure by which determined amounts of plasma (the fluid component of blood that contains phytanic acid) are removed from the blood and replaced with fluids or plasma that does not contain phytanic acid. Regular utilization of this technique allows people who fail to follow a restricted diet to maintain lower phytanic acid levels and experience less tissue damage and symptoms.

Patients with Refsum disease should be seen regularly by a multidisciplinary team of healthcare providers, including a pediatrician, neurologist, ophthalmologist, cardiologist, medical geneticist specializing in metabolic disease, nutritionist, and physical/occupational therapist. People with Refsum disease, or those who are carriers of the abnormal gene or who have a relative with the disorder, can be referred for genetic counseling to assist in making reproductive decisions.

Prognosis

The prognosis of Refsum disease varies dramatically. The disorder is slowly progressive and, if left untreated, severe symptoms will develop with considerably shortened life expectancy. However, if diagnosed early, strict adherence to a phytanic acid-free dietary regimen can prevent progression of the disease and reverse skin disease and some of the symptoms of peripheral neuropathy. Unfortunately, treatment cannot undo existing damage to vision and hearing.

Renal agenesis

Definition

Renal agenesis is the failure of kidney formation during fetal development. Renal agenesis can be unilateral, with one kidney present, or bilateral, with no kidneys or very little kidney present. The two types of renal agenesis have very different clinical courses, with unilateral agenesis being more favorable.

Description

Kidneys perform many important bodily functions. Having at least one kidney is necessary for life. Kidneys filter waste and extra fluid from the blood; keep a healthy blood level of electrolytes and minerals, such as sodium, phosphorus, calcium, and potassium; help to maintain healthy blood pressure; and release hormones that are important for bodily functions. Normally, there are two fist-sized kidneys present, one on each side of the spinal column at the back just below the ribcage. Each kidney contains microscopic filter lobules called nephrons that transfer bodily waste products from the bloodstream to the urinary system. Functional nephrons are critical for maintaining bodily functions and for eliminating the buildup of waste products that can be life threatening.

Unilateral renal agenesis

Unilateral renal agenesis results from defects in fetal development that cause only one kidney to form. Having a solitary kidney instead of two is not necessarily life-threatening. The solitary kidney usually enlarges, and is able to perform most bodily functions to a degree sufficient for life. When a solitary kidney does negatively affect health, it is through very subtle and gradual changes that may not be noticed initially. Over long periods of time, changes, such as an increase in blood pressure, may require specific preventive measures or treatments. Having a solitary kidney also means that if injury or disease leads to renal failure, there is no backup kidney to take over. In this circumstance, the consequences of a diseased unilateral kidney can be life threatening.

Bilateral renal agenesis

Bilateral renal agenesis is a genetic disorder involving the failure of both kidneys to form during fetal development. Fetal kidney development begins between five and seven weeks of gestation. During development, the fetus is cushioned, protected, and maintained at constant temperature in a substance known as amniotic fluid. Fetal urine production begins in early gestation and is responsible for the majority of the amniotic fluid present in the second and third trimesters of pregnancy. The fetus continuously swallows amniotic fluid, which is reabsorbed in the fetal gastrointestinal tract and excreted back into the amniotic cavity by the kidneys. Because amniotic fluid is maintained by fetal urine, a fetus with no kidneys has little amniotic fluid to surround and protect it in the amniotic sac. This condition is known as oligohydramnios, and results in physical compression of the fetus in the womb. Bilateral renal agenesis causes a set of physical complications known as Potter syndrome. While bilateral renal agenesis is not the only cause of Potter syndrome, the lack of both kidneys naturally results in Potter syndrome symptoms. Only 20% of all Potter syndrome cases are caused by bilateral renal agenesis. The amniotic membrane sticking to the fetus, and the compression, cause further physical malformations, including the squashed facial features characteristic of Potter syndrome.

Compression and lack of amniotic fluid also lead to a serious defect in lung development. The fetal urine is critical for proper lung development. Fetal urine helps to expand the airways and supplies the amino acid proline, a critical amino acid for lung development. Upon leaving the womb, an infant must rely on the lungs and on breathing air to receive oxygen for life. Alveoli are the many small sacs deep in the lungs that are responsible for exchanging oxygen with the blood. If the alveoli are underdeveloped (pulmonary hypoplasia) at birth, the infant cannot breathe properly and will go into respiratory

distress. In most cases, the condition is fatal within the first few months of postnatal life. The cause of death is pulmonary hypoplasia, with consequent respiratory insufficiency. There are rare cases in which a portion of one kidney has formed and some lung development occurs. These cases are also often fatal. If sufficient lung development is present, an infant with bilateral renal agenesis may be rescued through dialysis and eventual kidney transplant.

Genetic profile

Bilateral renal agenesis (BRA) is a rare condition thought to occur in sporadic and autosomal recessive forms. Sporadic forms of BRA have an unknown cause that may or may not be genetic. It is thought that BRA can be inherited in an autosomal recessive form, caused by the inheritance of two defective copies of a gene. Each parent contributes one copy of a gene. In autosomal recessive inheritance, if both copies are defective, the result is disease. If only one defective copy is present, the disease does not occur, but the defective gene can still be passed on to subsequent generations. If both parents are carrying a defective gene, each offspring has a one in four (25%) chance of inheriting the disease. Populations with a high frequency of healthy individuals carrying defective genes will also have higher prevalence of offspring with the disease.

BRA is also more common when a parent has a distinct kidney malformation, especially unilateral renal agenesis. Research has demonstrated that unilateral renal agenesis and bilateral renal agenesis are genetically related. For this reason, when bilateral renal agenesis is detected in an infant, an ultrasound is performed on the kidneys of parents and siblings. Approximately 9% of first-degree relatives of infants with bilateral renal agenesis have some type of asymptomatic renal malformation.

The exact genetic causes of both unilateral and bilateral renal agenesis were unknown. It is speculated that both conditions are caused by mutations in the genes involved in fetal kidney development. Normal fetal kidney development involves an essential interaction between the forming kidney buds (ureteric bud) and a tissue known as the metanephric mesenchyme. The interaction of the ureteric bud with the metanephric mesenchyme is necessary for kidney formation. The interaction is controlled by a combination of genes, cellular-signaling molecules that control gene expression (transcription factors), and cellular-signaling molecules that control cell growth (growth factors). Animal studies have identified several of the factors that can be mutated to cause renal agenesis. Research is ongoing to determine the cause in humans.

In 2014, researchers D. Y. Hwang et al. in China studied 650 families with congenital anomalies of the kidney and urinary tract (CAKUT), a condition that is present in approximately 50% of children with renal failure. CAKUT involves a spectrum of kidney anomalies including renal agenesis. They discovered mutations in the following genes: *BMP7*, *CDC5L*, *CHD1L*, *EYA1*, *GATA3*, *HNF1B*, *PAX2*, *RET*, *ROBO2*, *SALL1*, *SIX2*, and *SIX5* were associated with CAKUT in 41 of the 650 families. In another study of 590 families with CAKUT in China, researchers identified recessive genetic mutations in *FRAS1*, *FREM2*, *GRIPI*, *FREM1*, *ITGA8*, and *GREM1* associated with isolated CAKUT in 15 of the 590 families. Specifically, they identified recessive biallelic missense mutations in these six genes. Additional research has suggested that the vast majority of cases of renal agenesis showed a lack of obvious differences at the genome level and nongenetic factors are most likely involved in the pathogenesis of renal agenesis.

Demographics

Unilateral kidney agenesis is fairly common, occurring in approximately 1 per 1,000 live births in the United States. Bilateral renal agenesis occurs in 1 per 3,000 live births. There is no association of renal agenesis with race. Males have a higher rate of developing Potter syndrome than females. Individuals with bilateral renal agenesis present with the condition as neonates, whereas individuals with unilateral renal agenesis may not be aware of their condition even as adults. Unilateral renal agenesis is usually discovered in an adult undergoing tests for some other condition.

Signs and symptoms

Unilateral renal agenesis

Most people born with a solitary kidney do not experience any noticeable signs or symptoms that would indicate they have unilateral renal agenesis. A solitary kidney is usually discovered when the individual is having ultrasound imaging or surgery for some other problem. However, having unilateral renal agenesis can cause gradual changes in bodily functions that lead to unhealthy clinical conditions. A potential complication of a solitary kidney is high blood pressure.

Kidneys normally contribute to maintaining a healthy blood pressure in two ways. Kidneys regulate how much fluid flows through the bloodstream and how much fluid is excreted from the body. The more fluid that flows through the bloodstream, the more the blood pressure increases. Kidneys also release a hormone called renin that works as part of a team of hormones to expand or contract blood vessels. The more contraction of blood vessels there is, the higher the blood pressure. Many

individuals who are born with a solitary kidney eventually develop slightly higher blood pressure.

In addition, one kidney doing the work of two kidneys can cause more wear and tear than normally would occur. A solitary kidney may eventually be slightly damaged, causing excessive protein to be excreted from the body through the urine. This condition is known as proteinuria, and is a sign of kidney damage. Another potential complication of having a solitary kidney is reduced efficiency at removing waste from the bloodstream. The portion of the kidney that acts as a filter is the glomerulus. A reduced ability to filter the blood is known as a reduced glomerular filtration rate (GFR), a potential complication of unilateral renal agenesis. As long as these complications are controlled, individuals with a solitary kidney often experience no actual symptoms.

Bilateral renal agenesis

There are many signs of bilateral renal agenesis during neonatal (first six weeks of life) care. Potter facies are facial features associated with Potter syndrome from bilateral renal agenesis. The facies include a squashed facial appearance, flattened nose, recessed chin, prominent epicanthal folds (fold of skin from root of nose to eyebrow), and low-set abnormal ears. A poor or absent urine output during the first 48 hours of life, respiratory distress, and poorly developed lungs are all indicative signs. The degree of lung development corresponds with the extent and duration of the oligohydramnios. Respiratory distress is often the cause of death.

Diagnosis

Unilateral renal agenesis

A diagnosis of unilateral renal agenesis can be made using various imaging techniques such as an ultrasound, or directly through surgery. Diagnosis of unilateral renal agenesis is usually made in asymptomatic adults, while they are investigating some other condition. Complications of unilateral renal agenesis may include proteinuria and reduced GFR. A diagnosis of proteinuria is made through urinalysis. High levels of protein in the urine indicate kidney damage. Highly sensitive urinalysis tests are also performed to diagnose proteinuria. These tests calculate the protein-to-creatinine ratio. A high protein-to-creatinine ratio in urine indicates that the kidney is leaking protein that should be kept in the blood, and indicates kidney damage. The GFR can be measured by injecting a contrast medium into the bloodstream. The injection is followed by a 24-hour period of urine collection to determine how much of the medium was filtered through the kidney. A more recent method of determining GFR is by measuring blood creatinine levels and performing

KEY TERMS

Amniotic sample—Sample of amniotic fluid, the protective fluid surrounding a fetus in the womb.

Anemia—Condition in which there are low levels of red blood cells.

Asymptomatic—Without symptoms.

Biallelic—Pertaining to both pair of genes or alleles in a set.

Creatinine—A normal component of blood kept in low levels in urine by functioning kidneys.

Dialysis—Filtering of blood to remove waste products that the kidneys would normally remove if they were present and functioning.

DNA—Deoxyribonucleic acid, inheritable material that constitutes the building blocks of life.

Gastrointestinal tract—The food intake and waste export system that runs from the mouth, through the esophagus, stomach, and intestines, to the rectum and anus.

Growth factors—Cellular-signaling components that stimulate cell division or other cell processes.

Missense—A portion of mRNA in which the coding is changed because of an abnormal change in the protein base sequence.

Neonate—A newborn infant up to six weeks of age.

Oligohydramnios—An abnormally small amount of amniotic fluid.

Pulmonary hypoplasia—Underdevelopment of the lungs.

RNA—Ribonucleic acid, the intermediate step between DNA and its final expression product. DNA is transcribed into RNA and RNA is translated into protein.

Transcription—The process by which DNA is changed into RNA.

Transcription factors—Cellular-signaling components that cause the transcription of a gene.

calculations that involve weight, age, and values assigned for sex and race. If GFR remains consistently below 60, a diagnosis of chronic kidney disease is made.

Bilateral renal agenesis

Bilateral renal agenesis is investigated if there is a history of oligohydramnios, prenatal sonograms depicting renal agenesis, or unilateral renal agenesis in the family. If

an infant has bilateral renal agenesis, blood tests will show altered levels of electrolytes and minerals that the kidney typically filters and normalizes. Renal function and GFR can be assessed through measuring blood levels of creatinine. Urinalysis, if any urine is present, is used to detect proteinuria. Ultrasound imaging can reveal renal agenesis both before and after birth, but the prenatal condition is not as easily visualized. Chest x-rays, although undesirable in an infant, can be used to assess lung development. In neonates who die from this condition, an autopsy is recommended to confirm the diagnosis.

Treatment and management

Unilateral renal agenesis

No treatment is necessary for unilateral renal agenesis other than controlling complications if they arise. Kidney function is monitored by regular physical examinations that check blood pressure and blood and urine tests. These tests are usually done once a year, and are designed to assess whether the unilateral kidney is functioning properly. Regular monitoring is critical because if the solitary kidney becomes diseased or damaged, there is no backup kidney available to maintain life.

Normal blood pressure is defined as a measurement of 120/80 or lower. High blood pressure is defined as a measurement of 140/90 or higher. Individuals with unilateral renal agenesis are advised to maintain blood pressure levels below 130/80 to prevent kidney damage. If medication is required to control blood pressure, individuals with unilateral renal agenesis may need blood pressure medications that also protect kidney functions. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers are two classes of blood pressure medication that can also protect kidney function and reduce proteinuria. Diuretics may also be used to help lower blood pressure by removing excess fluid from the body.

Individuals with unilateral renal agenesis do not need to follow a special diet, but should limit daily sodium intake to avoid developing high blood pressure. While a special diet is not required, some methods of dieting are contraindicated. High-protein diets are not advised for individuals with unilateral renal agenesis. Because protein breakdown products add stress to the kidneys as they remove waste from the bloodstream, excessive protein intake puts an extra burden on the solitary kidney. Normal, moderate amounts of protein intake are recommended in unilateral renal agenesis. Alcohol and caffeine intake should also be limited. Individuals with unilateral renal agenesis are often advised to avoid contact sports unless protective gear is worn. Damage to the single functional kidney could quickly become life threatening.

Bilateral renal agenesis

Neonates born with bilateral renal agenesis are immediately placed in the neonatal intensive care unit. The level of renal and respiratory function is immediately assessed. Evaluation is also made of any other malformations in bodily systems. Once the long-term prognosis of survival is determined, a treatment plan can be addressed. If a neonate with bilateral renal agenesis has severe respiratory distress from severe pulmonary hypoplasia, no further treatment may be the decided course of action. If lung development is sufficient to respond to treatment, mechanical ventilation can supply respiratory support. Management of renal failure involves a complex course of action taken to address all the consequent complications. Adequate nutrition with restricted sodium and fluid intake may be achieved through a nasogastric feeding tube. Medications and vitamin supplementation can be used to address electrolyte imbalances from lack of kidney function. Because the kidney is responsible for vitamin D formation, vitamin D therapy is important. Calcium carbonate is also supplemented because the kidneys are not present to regulate calcium levels in the blood.

Children with chronic renal failure often have poor growth and require supplemental human growth hormone (Genotropin, Humatrope, Nutropin). Human growth hormone stimulates the growth of bone, skeletal muscle, and organs. Human growth hormone acts in conjunction with another medication, erythropoietin, to increase the number of red blood cells and address the additional complication of anemia. Anemia occurs because the kidneys are not present to produce erythropoietin, which is responsible for the stimulation of red blood cell production in the bone marrow. Epoetin alfa (Epogen, Procrit) is a synthetic form of erythropoietin used in the treatment of bilateral renal agenesis. Anemia is also treated with iron supplements, which can be given orally or administered through an injection.

Renal failure causes hypertension; infants with bilateral renal agenesis may require hypertension medications in addition to restricted sodium and fluids. In renal failure, hypertension is caused by fluid overload. To treat the hypertension associated with bilateral renal agenesis, diuretic agents (Lasix) are used. Diuretic agents promote the excretion of water and electrolytes from the body. They decrease blood pressure by decreasing the amount of fluid present in the blood vessels. Other hypertensive medications may also be used, as is appropriate for the patient's age. Dialysis is required to function as a blood filter replacement for the kidney. Frequent dialysis treatments remain necessary until the infant is old enough to receive a kidney transplant.

Prognosis

In the absence of kidney injury or disease, the prognosis for unilateral renal agenesis is excellent. Individuals

with unilateral renal agenesis usually lead normal, healthy lives. Avoidance of injury and basic health practices are important to maintain this quality of life.

Bilateral renal agenesis has a very poor prognosis. It is usually fatal in the first few days of life. The usual cause of death is respiratory failure and acute renal failure during the neonatal period. If survival progresses to early childhood, patients may have chronic lung disease or chronic renal failure. If the lungs have sufficient development, a kidney transplant is necessary for survival. After a kidney transplant, the prognosis is improved.

Renal failure due to hypertension

Definition

Renal failure (kidney failure) is caused primarily by chronic high blood pressure (hypertension) over many years. Hypertension is the second major cause, after diabetes, of end-stage renal disease (ESRD) and is

responsible for 25%–30% of all reported cases. In addition, many people with diabetes also have hypertension, thus high blood pressure plays an even larger role in kidney failure. Renal failure due to hypertension in its inherited form is also known as familial nephropathy.

Description

Hypertension is a chronic, persistent increase in blood pressure that can be due to many factors such as diet, lifestyle, and a genetic predisposition. Chronic hypertension causes a physiological change in the arteries of the body, decreasing their ability to pump blood correctly. The kidney may be seriously affected by hypertension if the structures of the renal arteries are compromised due to hypertension. If the arteries are not functioning correctly, the organ will not function properly either, possibly leading to renal failure. Diabetic nephropathy and hypertensive nephropathy are the two most common causes of end-stage renal failure. There is still controversy regarding the genetic component of renal failure due to hypertension, but with the recent advances in genome sequencing, more studies can be performed to determine the exact cause.

Genetic profile

It is believed that most cases of hypertension leading to kidney failure have a genetic element. Finding a genetic link is complicated by the fact that nearly half of all people with renal failure have three or more serious disorders, such as diabetes. Animal studies have been done to find genetic linkages to hypertension and kidney failure, but genetic studies on humans are in their infancy. A recent breakthrough came in a study of African American subjects with hypertensive end-stage renal disease. Researchers found a significant association between severe hypertension and mutations on the *HSD11B2* gene located at position 16q22.1. This is a

Light micrograph of a kidney displaying hypertrophy (enlargement) of its walls because of high blood pressure (hypertension). (Voisin/Phanie/Science Source)

KEY TERMS

Dialysis—Process by which special equipment purifies the blood of a patient whose kidneys have failed.

Nephropathy—Kidney disease.

Proteinuria—Excess protein in the urine.

Serum creatinine—A chemical in the urine of kidney patients used to determine kidney disease and failure. Elevated levels of serum creatinine are an early marker for severe kidney disease or failure.

Transplantation—The implanting of an organ from either a deceased person (cadaver) or from a live donor to a person whose organ has failed.

gene that plays a role in sodium retention and the inter-conversion between cortisol and cortisone. The mutation of this gene is typically inherited in an autosomal dominant pattern.

In another study, researchers studied an Israeli family of Iraqi-Jewish origin whose members suffered from hypertension and renal failure. The researchers found a genetic locus at 1q21 that was autosomal dominant. They also hypothesized that the gene encoding *atrial natriuretic peptide receptor 1 (NPR1)* was the disease gene that led to the hypertension/renal failure.

Other families with high rates of hypertension have also been studied. For example, researchers observed a family of Old Order Amish in Lancaster, Pennsylvania, and found a genetic link for hypertension to chromosome 2q31-34. The subjects were not experiencing kidney failure, thus, further study would be needed to determine if the identified genetic locus also coded for ESRD.

Animal models are also indicating that genes associated with the coding of *HNF1*, a transcription factor related to disorders such as renal cell carcinoma and diabetes mellitus, may be associated with hypertension affecting the kidney.

Demographics

People of all ages, races, and both sexes may develop kidney failure due to hypertension. However, some groups are at much greater risk than others. African Americans are at particularly high risk for both hypertension and renal failure, and have three and a half times the number of ESRD cases as Caucasians. They also experience kidney failure at a younger age, with an onset at about age 56 compared to an onset at age 62 for Caucasians. African Americans also have a higher rate of

diabetes than non-African Americans, another reason for their increased risk for kidney failures. Native Americans and Alaskan Natives are also at high risk for ESRD. There are about the same number of males and females with newly diagnosed ESRD.

In 2012, there were 636,905 prevalent cases of ESRD due to hypertension in the United States, up 3.7% from the previous year. The risk increases with age, with environmental factors, and in combination with other disorders such as diabetes and other metabolic disorders.

Signs and symptoms

Universal symptoms of ESRD are severe fatigue, fluid retention (edema), and elevated blood pressure readings. Other symptoms include a failure to eat (anorexia) and skin color changes such as a change to a yellow-brown skin color. Urea from perspiration may appear on the skin as whitish crystals, similar to frost. Pruritus (severe itching of the skin) is common. Patients may have muscle cramps and convulsions. Many have malnutrition from anorexia and vomiting. Gastric ulcers are common, as are cardiac symptoms stemming from the retention of sodium and water. Anemia (low levels of iron in the blood) is also common.

Diagnosis

Diagnosis is based on the results of a physical examination and laboratory blood and urine tests. A patient who has end-stage renal disease looks very ill and has obvious fluid retention and clear indicators of severe disease. Anemia is common. Blood pressure is elevated, and even patients who did not have hypertension prior to the onset of ESRD will develop hypertension. Patients also usually have massive amounts of protein in the urine and high levels of serum creatinine. Urea levels are also raised.

Treatment and management

Once physicians diagnose end-stage renal disease, they must make a plan for dialysis. In addition, patients may be placed on restricted fluids. Anemia is treated and transfusions are given if anemia is severe. ACE inhibitor drugs may be prescribed at low doses to treat cardiac symptoms. Diuretics may be prescribed to reduce fluid retention. Multivitamins may be recommended because of food restrictions.

All patients with kidney failure, despite the cause of the failure, must receive kidney dialysis or kidney transplantation. Eventually, those on dialysis will require transplantation of a kidney, either from a recently deceased person or a live donor. (Each person has two

QUESTIONS TO ASK YOUR DOCTOR

- What are the characteristics of end-stage renal disease, and how is that condition related to hypertension?
- What evidence is there for the hypothesis that hypertension is at least partially a genetic disorder?
- Can hypertension be diagnosed prenatally or in newborn infants?
- What lifestyle choices can a person make to help control the progress of hypertension?

kidneys and can live normally with only one kidney.) About 13,000 kidney transplants are performed in the United States each year and about 47,000 people wait for a donated kidney each year.

There are two types of dialysis. The most common type of treatment is “hemodialysis,” a procedure that uses a machine called a dialyzer to clean and filter the blood, since the kidneys can no longer perform that function. A connection from the machine is made to the patient’s bloodstream and the blood travels through the dialyzer where it is cleaned for 2–4 hours. This procedure is generally performed three times a week. Patients must also change their diets to carefully limit the amount of salt, potassium, and fluids that are consumed, among other dietary restrictions that are given.

Peritoneal dialysis is another option for patients with kidney failure. In this procedure, the patient’s own abdominal lining (the peritoneal membrane) is used to help clean the blood. Rather than the patient’s own blood traveling to a machine, as with a dialyzer, a cleansing solution is transferred through a special tube (catheter) directly into the body. The catheter remains in the body. The number of treatments and time to perform the cleansing procedures varies.

Prognosis

Most patients will eventually need a transplanted kidney to continue to live. The survival rate for those on kidney dialysis after 1 year is about 80% and after 2 years, about 66%. However, the 5-year survival rate with dialysis is 29%, and the 10-year survival rate is only 8%.

In contrast, the survival rate for those who receive a transplanted kidney from a deceased person is 94% after 1 year, 92% after 2 years, and 80% after 5 years. The 10-year survival rate with a cadaver transplantation is

57%. The survival rates are higher when the kidney is from a live donor; for example, the survival rate after 5 years with a live donor kidney is 89% and about 77% after 10 years.

Renal-hepatic ciliopathy

Definition

Renal-hepatic ciliopathy refers to the ciliopathic disorders affecting the kidneys and liver. Ciliopathies are genetic disorders that stem from mutations in genes associated with primary cilia-cellular organelles that are required for sensing the environment and controlling molecular signaling pathways. Recent findings have shown that a number of genetic disorders that were not previously thought to be related may be linked by root causes in cilia-dependent dysfunctions.

Description

Nephronophthisis-related ciliopathies (NPHP-RC) are a group of rare autosomal recessive cystic kidney

KEY TERMS

Ciliopathy—A range of genetic disorders caused by mutations in cellular cilia, basal bodies, or by changes in ciliary function.

Cilium—A slender protuberance from a larger cellular body. Required for sensing environmental and chemical stimuli, controlling signaling and developmental pathways. Plural: cilia.

Hepatic—Pertaining to the liver.

Nephronophthisis—An autosomal recessive genetic disorder of the kidneys that usually affects children.

Renal—Pertaining to the kidneys.

Wnt Signaling—A signal transduction pathway that functions to pass signals from the outside of the cell to the inside of the cell. Signals are transduced through the binding of proteins to receptors on the plasma membranes of cells. The receptor then transfers the signal to additional signaling proteins that function inside the cell. Wnt signaling pathways regulate cell shape and growth, cell polarity, and cell-cell communication, among other required cellular mechanisms.

disorders. Most NPHP affect children, and while rare among the general population, they are the most common cause of kidney failure in children. It is expected that only 0.9 in a million people in the United States have NPHP. NPHP-RC include diseases such as Senior-Loken syndrome, which is a ciliopathy that can affect the eyes as well as the kidneys; Joubert syndrome, which affects the development of the cerebellum; and Meckel-Gruber syndrome, a multi-organ ciliopathy that is characterized by renal cystic dysplasia, polydactyly, central nervous system deformities, and hepatic developmental defects. NPHP is the most common genetic cause of end-stage renal failure and is characterized by many histological abnormalities as well as organ function problems.

Because primary cilia play such a diverse role in many different tissue types, ciliopathic diseases can have a wide range of symptoms and affect otherwise seemingly unrelated organs.

Genetic profile

Ciliopathies are most commonly autosomal recessive and can affect males and females equally. The majority of cases results from a family history of

disease, but about 5%–10% can occur from spontaneous *de novo* mutations.

Renal ciliopathies are the most common of the childhood-onset ciliopathies, occurring in 1 out of 20,000 live births. While most renal ciliopathic disorders are recessive, there are some cases where they can be autosomal dominant, especially if the mutation occurs in germ-line cells. Even in these cases, renal cysts only form in about 5% of cells that acquire a second mutation.

Hepatic ciliopathies show similar prevalence in both men and women, but cysts tend to be exaggerated in female patients, particularly if the woman has had multiple births or has used oral contraception. The majority of liver disorders are caused by mutations in ciliary proteins.

Demographics

Ciliopathy has been recorded in all ethnicities and generally affects men and women alike.

Signs and symptoms

In the cases of ciliopathies that affect the liver and kidneys, common symptoms include decreased urine concentration and the formation of cysts on the organs; this may or may not affect organ function and can often cause discomfort or abdominal pain. Because important cellular signaling is disrupted in ciliopathies, flaws in cell development alter how organs grow and function. It is also characteristic for multiple organs to be affected in ciliopathic disorders.

In patients with NPHP, approximately 15% exhibit renal failure or dysfunction, liver malformation, retinal dystrophy, or cerebellar hypoplasia. All these symptoms are due to the incomplete or incorrect development of organs because of mutations in proteins that localize to primary cilia and are required for cell differentiation and development.

Diagnosis

Congenital symptoms are associated with renal-hepatic ciliopathies and can include brain defects, extra fingers, and retinal degeneration. These characteristics can usually be seen early in life, if not prenatally. For those who know ciliopathic disorders run in their family, a family history can be developed, and potential inheritance probabilities can be calculated. Those who are born with or develop renal-hepatic disorders rely on palliative treatment to maintain organ function and for pain management.

Due to recent findings that many genetic disorders are related to mutations in ciliopathic proteins, there has

QUESTIONS TO ASK YOUR DOCTOR

- Relatives in my family have a ciliopathic disease. Is it possible that I could be a carrier?
- My child has been diagnosed with kidney disease; what form of the disease do they have and is there a course of treatment?
- I have a ciliopathic disease; can I pass it on to my children?
- What other disorders might be linked to the ciliopathic disease I have been diagnosed with?

been a developing interest in identifying not only more of the genes related to ciliopathies but also in the identification of their functions. To date, over 90 genes are associated with recessive mutations that cause ciliopathies; a better understanding of what roles the encoded proteins play in development could lead to more specialized treatments for ciliopathic disorders.

In one such study of 1,056 members of a family with NPHP-RC, 50% of the cases were due to a mutation in a gene whose function is unknown. Homozygosity mapping and sequencing were used to ID more genes that are associated with NPHP. The gene *DCDC2* was identified as one such gene that causes a renal-hepatic variant of NPHP-RC. *DCDC2* localizes with other NPHP-RC genes in primary cilia and interacts with DVL (Disheveled), a mediator of Wnt signaling. It is thought that *DCDC2* regulates cell division through its direct interaction with the Wnt signaling pathway. These results show that defects in Wnt signaling play a central role in NPHP-RC, and this identification opens the door to potential specialized treatment of the disease.

Treatment and management

Treatment is limited to dialysis or transplant for those whose kidneys fail due to ciliopathic disease. In some cases of hepatic ciliopathy the liver functions properly, but cyst development can affect quality of life. Cysts can be removed surgically but often grow back.

Some ciliopathies affect brain development, which can lead to learning and physical disabilities depending on the area of the brain that is most affected. In such cases, physical and educational therapies can be utilized to mediate or improve the patient's quality of life.

Prognosis

Because the symptoms and severity of ciliopathic diseases can vary so much, the prognosis can be unique to each individual case.

Renpenning syndrome

Definition

Renpenning syndrome is an inherited X-linked disorder that manifests itself in males. It is characterized by intellectual disability, short stature, a smaller than normal head circumference (microcephaly), and small testes. Hans Renpenning first described the syndrome in 1962 in a large Mennonite family living in Manitoba, Canada. The term "Renpenning syndrome" came to be used as a general designation for X-linked intellectual disability. However, as the syndrome has been mapped to Xp11.2-p11.4, the term "Renpenning syndrome" should be limited to the condition that maps to this region and is characterized by severe intellectual disability, microcephaly, short stature, and small testes. Its prevalence is unknown.

Description

Renpenning syndrome is among the group of genetic disorders known as X-linked intellectual disability (XLMR) syndromes. Developmental delay is present early, with males learning to walk at age 18–24 months

Renpenning syndrome is a form of intellectual disability linked to a gene abnormality on the X-chromosome. (Creations/Shutterstock)

KEY TERMS

Microcephaly—An abnormally small head.

Renpenning syndrome—X-linked intellectual disability with short stature and microcephaly not associated with the fragile X chromosome and occurring more frequently in males, although some females may also be affected.

Short stature—Shorter than normal height, can include dwarfism.

Small testes—Refers to the size of the male reproductive glands, located in the cavity of the scrotum.

X-linked intellectual disability—Subaverage general intellectual functioning that originates during the developmental period and is associated with impairment in adaptive behavior. Pertains to genes on the X chromosome.

and able to say simple words at age 3–4 years. Although an affected male may appear physically normal, his head circumference and height will be at the lower limits of normal. After puberty, testes will be smaller than normal. Diagnosis is very difficult, especially if there is only one male with intellectual disability in a family. The diagnosis is exclusively based on evidence of inheritance of the above clinical findings in an X-linked manner and localization to the short arm (Xp11.1-p11.4) of the X chromosome.

Genetic profile

Renpenning syndrome is caused by an alteration in the *PQBPI* gene located on the short arm (Xp11.2-p11.4) of the X chromosome and encodes the protein polyglutamine-binding protein 1. The function of polyglutamine-binding protein 1 is not well defined but is thought to be important in RNA processing and transport. Most of the mutations in *PQBPI* in cases of Renpenning syndrome produce a truncated protein that does not function properly or has partial function that interferes with the normal protein.

The altered gene in affected males is inherited from their mother, if she is a carrier for the mutation. Since males have only one X chromosome, a gene mutation on the X is fully expressed in males. Carrier females, with one normal X chromosome and one affected X chromosome, do not have any of the phenotype associated with Renpenning syndrome.

Female carriers have a 50% chance of transmitting the altered gene to a daughter or a son. A son inheriting the altered gene will have Renpenning syndrome and will likely not reproduce.

Demographics

Only males are affected with Renpenning syndrome. Carrier females do not express any of the signs or symptoms. Renpenning syndrome is a rare disorder and its prevalence across race and nationality is unknown. In the 15 families where it has been observed, more than 60 individuals have been identified.

Signs and symptoms

Manifestations of Renpenning syndrome may be present at birth. One male was reported to have global developmental delay at birth. All affected males had delay in reaching developmental milestones—walking at age 18–24 months and having little or no speech by age 3.

Affected males have a small head circumference (microcephaly), are of short stature, and have small testes. Facial features may include central balding, an upward slant to the eyes, and a short distance between the nose and the upper lip. Other clinical findings present in some of the affected males are blindness, seizures, and diabetes mellitus.

Mental impairment is severe, with IQ ranging from 15 to 40.

Diagnosis

The diagnosis of Renpenning can tentatively be made on the basis of the clinical findings, including an analysis of the family history for evidence of X-linked inheritance. Linkage or segregation analysis using DNA markers could possibly rule out other X-linked intellectual disability syndromes. Unfortunately, there are no laboratory or radiographic changes that are specific for Renpenning syndrome.

Sutherland-Haas syndrome, another X-linked intellectual disability syndrome, also has microcephaly, short stature, small testes, and upslanting of the eye openings. Furthermore, this syndrome is localized from Xp11.3 to Xq12, which overlaps with the localization of Renpenning syndrome. However, males with Sutherland-Haas also have spasticity, brachycephaly (disproportionate shortness of the head), and a thin appearance. It is possible these two syndromes have different mutations in the same gene.

The mutation that causes Chudley-Lowry syndrome, which also has microcephaly, short stature, and small testes, has yet to be identified. However, males have distinct

QUESTIONS TO ASK YOUR DOCTOR

- What does it mean to say that Renpenning syndrome is an “X-linked” genetic disorder?
- What physical and mental characteristics are typically associated with Renpenning syndrome?
- Do carriers for Renpenning syndrome exhibit any signs or symptoms related to the disorder?
- What treatments are available for the disease or related medical conditions?
- If Renpenning syndrome occurs in my family and I am a woman, how likely is it that I am a carrier?

facial features similar to those observed in XLMR-hypotonic faces, and obesity. As this syndrome has not been mapped it is possible that Chudley-Lowry syndrome results from a mutation in the same unknown gene responsible for Renpenning syndrome.

Three other X-linked intellectual disability syndromes (Borjeson-Forssman-Lehman, X-linked hereditary bullous dystrophy, and XLMR-hypotonic facies) have microcephaly, short stature, and small testes. However, these conditions are located in different regions on the X chromosome and can be ruled out if DNA marker analysis is done in the family.

Treatment and management

Treatment for Renpenning syndrome is supportive. Early educational intervention may prove to be of some benefit for affected males. Some males have been reported to have seizures or diabetes mellitus; medication to control these conditions may be required at some point. In more severe cases, individuals with the syndrome may eventually have to live in facilities outside the home.

Prognosis

Life-threatening or other health concerns have not been associated with Renpenning syndrome. However, the presence of severe mental impairment likely will result in some affected males living in a more controlled environment outside the home.

Retinitis pigmentosa

Definition

Retinitis pigmentosa (RP) refers to a group of inherited disorders that slowly lead to blindness due to abnormalities of the photoreceptors (primarily the rods) in the retina.

Description

The retina lines the interior surface of the back of the eye. The retina is made up of several layers. One layer contains two types of photoreceptor cells referred to as the rods and cones. The cones are responsible for sharp central vision, distinguishing and recognizing colors, and seeing fine details. The cones are primarily located in a small area of the retina called the fovea.

The area surrounding the fovea and on the perimeter of the retina contains the rods, which are necessary for vision on the sides, as well as vision in dark and dimly lit conditions. The number of rods increases in the periphery.

The rod and cone photoreceptors normally convert light that enters the eye into electrical impulses; these

A retinal photograph showing retinitis pigmentosa. The disorder first affects night vision and peripheral vision. (J. Cavallini/Custom Medical Stock)

impulses are sent to the brain along the optic nerve at the back of the eye and an image is recognized by the brain. Another layer of the retina is called the retinal pigmented epithelium (RPE).

In RP, the photoreceptors begin to break down and lose their ability to function. The rods are primarily affected, and as a result it becomes difficult to see in dim light and in the peripheral areas. The ability to see color is also lost in some cases. In the late stages of the disease, only a small area of central vision remains and this can also be lost.

There are many forms of retinitis pigmentosa and all of them are genetic. Sometimes the disorder is classified by the age of onset or by the inheritance pattern. RP can also be part of a medical syndrome, in which other medical problems are present. This entry focuses on nonsyndromic RP, the type that is not associated with other medical complications.

Genetic profile

RP is an inherited disease associated with different inheritance patterns. It is felt that as many as 100 genes can cause the various types of the condition. The RP may be a familial condition, in which multiple family members are affected. It may also be isolated (or simplex), in which there is only one person with RP in the family. People with isolated RP represent 10%–40% of all cases. Some of these may be the result of new gene changes (or mutations). Other isolated cases are those in which the person has a relative with a gene mutation, but that relative has no obvious signs of RP.

RP is most commonly inherited as an autosomal dominant, autosomal recessive, or sex-linked condition

in a family. Autosomal dominant RP (ADRP) occurs in about 15%–25% of affected individuals. At least 14 different genes have been identified as causing ADRP, with significant ones called the *RHO*, *RP1*, *RDS*, and *ROM1* genes. People with ADRP often have an affected parent and other relatives in multiple generations. Someone with ADRP has a 50% chance to have a son or daughter with the same type of RP.

Autosomal recessive RP (ARRP) occurs in about 5%–20% of affected individuals. At least 22 genes have been identified that cause this type of RP, including significant ones called *RPE65*, *PDE6A*, and *PDE6B*. In ARRP, each parent of the affected person is a carrier of a gene mutation that causes ARRP. Neither of these parents has symptoms of ARRP, and they have a 25% chance to have an affected son or daughter in every pregnancy together. All of the children of someone with ARRP would be a carrier for the condition.

Five to fifteen percent of people with RP have the sex-linked form of recessive RP, which is most often X-linked recessive RP (XLRP). At least five genes have been identified with XLRP, with the most significant called *RP2* and *RP3*. Males are usually more affected than females with XLRP and females carry an XLRP mutation on their X chromosome. Carrier females may not have signs of XLRP or they may have mild symptoms. In some cases, carriers have serious vision loss associated with XLRP. A female carrier's sons have a 50% chance of being affected, and her daughters have a 50% chance to be carriers. For a male with XLRP, his daughters would all be carriers, but none of his sons would be affected. RP is rarely inherited in an X-linked dominant manner. The risks to family members are very similar to XLRP, but females typically have some symptoms of RP instead. The family history pattern can be very similar to ADRP, and the difference may only be the gene mutation causing the RP in the family.

Rarely, RP is inherited by gene mutations in the *MTTS2* gene. This gene is located in the cell's mitochondria, as opposed to the cell's nucleus like all of the other genes. When the *MTTS2* gene is involved, only a female's sons and daughters would be at risk for RP. If a male has RP caused by the *MTTS2* gene, his children would not be at risk for RP.

Also very rarely, RP is caused by the involvement of both the *RDS* gene and the *ROM1* gene in the same family. An individual with RP may have a mutation in each of these genes. The risks to family members would be similar to those found in ADRP.

KEY TERMS

Amniocentesis—A procedure involving removal of a small amniotic fluid sample during pregnancy to obtain fetal genetic results.

Choroid—Layer of tissue underneath the retina.

Fundus—The interior back wall of the eyeball.

Melanin—Colored pigment that is naturally present in the eye.

Mitochondria—Structures within the cell responsible for making energy; contain their own genetic material, which is inherited through females.

Nucleus—Structure within the cell that contains most of a person's genetic material.

Ophthalmoscope—An instrument with special lighting, designed to view structures in the back of the eye.

Optic nerve—Nerve at the back of the eye that connects the retina to the brain.

Photoreceptor—Cells at the back of the eye that process the light that hits them; examples are cone and rod cells.

Demographics

RP is the most common form of blindness in people between the ages of 20 and 60 years old. It is thought to affect about 1.5 million men and women worldwide and approximately 1 out of every 3,500 to 4,000 people in the United States and Europe. For other parts of the world, there are no published data on exact prevalence, but RP is seen in all ethnic groups.

Signs and symptoms

The first symptoms are typically difficulties seeing in dimly lit conditions or night blindness. People may notice that they are uncomfortable with an oncoming car's bright headlights when driving at night, or they may have a hard time finding their seat in a darkened movie theater. People may begin to notice this as young as in childhood, adolescence, or later on in adulthood. In general, the earlier one notices this the more severe their RP may be over time. XLRP is usually associated with a more severe progression of symptoms than other forms of RP.

Eventually, people with RP experience a loss of peripheral vision and this may first start in childhood or early adolescence. This peripheral visual field loss typically progresses to tunnel vision, akin to seeing the world through two narrow straws. Prior to complete constriction

of their visual fields, people with undiagnosed RP may be considered clumsy by those who know them, because they may not see the things that are in the normal visual field.

People with RP usually maintain crisp central vision for a very long time, because the cones are not usually involved until the later stages of the condition. Once the cones become involved, people may have their central vision affected, with difficulty distinguishing colors. Occasionally, the loss of the ability to see color occurs before the loss of peripheral vision. Additionally, RP sometimes significantly affects one's visual acuity; men with XLRP may have a visual acuity less than or equal to that of legal blindness.

Specific changes in the eye are consistent with RP. In the early stages of RP, visual testing indicates abnormal rod functioning, but there may be no physical changes in the retina. People may see occasional flickering or small lights flashing in their eyes. Over time this can progress. There may be narrowing to the blood vessels in the retina, fine dust-like coloring within the retina, and floating in the eye's natural liquid. There is often loss of pigment from the layer of tissue underneath the retina. As the rods break down, clumps of dark-colored melanin cause a bone spicule formation along the retina's periphery. These are very characteristic of RP. Eventually, the optic nerve and retinal blood vessels can become pale in color. Others may have white dots deep in the retina, and other abnormalities of the optic nerve.

Those with RP often develop a specific type of cataracts, known as a posterior subcapsular cataract (PSC). These are different than the cataracts found in the general population. PSCs have a yellowish crystal-like appearance in the eye's lens, and this looks different than typical cataracts seen in those without RP. These cataracts may be removed by an ophthalmologist, but this does not help tunnel vision or night blindness.

People with RP usually have these changes in both of their eyes. However, some only have them in one section or one-half of an eye. This is called sector RP. People with this usually have no problems with night blindness, though visual testing can identify abnormal rod and cone functioning. Sector RP usually is inherited in a dominant manner, but is also seen in some female carriers of XLRP.

Diagnosis

A diagnosis of RP is usually made based on analysis of a person's symptoms, visual test results, and family history. Genetic testing is available for some types of RP.

When a person complains of problems with night vision, an ophthalmologist or optometrist usually

performs a careful eye examination, including pupil dilation, to determine if there are physical changes to the retina and back of the eye that are suggestive of RP. Other retinal problems can cause night blindness and must be ruled out. However, these may not have the retinal changes that are typical of RP. A careful eye examination can also determine one's visual acuity and color vision.

An electroretinogram (ERG) tests how well the photoreceptors in the retina are functioning. Specifically for RP, this test is very good at identifying how well the rod cells are working. It can also show how well the cone cells are working. A dark adaptation curve (DAC) test can document the exact amount of time one's eyes take to adjust to darkness.

Testing of the visual fields can determine how much is being seen from left to right, and up and down. The full field of vision is studied to identify any blind spots or clarify whether the central vision is affected.

Fluorescein angiography (FA) can be helpful to determine whether blood flow is normal throughout the back of the eye. These detailed photographs of the eye's blood vessels can help identify any circulatory problems at the back of the eye, as well as changes in the retina's structure.

Fundus photographs can be taken to document changes in the eye structure, shape, and color.

A consensus conference documented by Marmor et al. in 1983 established criteria to diagnose RP. They are:

- Rod dysfunction as measured by DAC or ERG
- Progressive loss in photoreceptor function
- Loss of peripheral vision
- Involvement of both eyes

Other eye conditions can mimic RP but do not have the specific eye changes and visual test results of RP. Gyrate atrophy of the choroid and retina, a recessive disorder, may seem like RP in its symptoms. However, it may be associated with round patches affecting the choroids and retina, which occur in the middle of the retina. Choroideremia, an X-linked recessive disorder, causes progressive blindness. However, it usually causes fine dark lines and patches on the choroids, which progress into pale yellow areas.

Leber congenital amaurosis is a group of recessive retinal abnormalities that cause serious vision problems or blindness that appear at or shortly after birth. Children affected with this condition usually have roving eye movements. Cone-rod dystrophy is a retinal problem in which the rods function well, but the cones progressively

QUESTIONS TO ASK YOUR DOCTOR

- What tests will you have to conduct to determine whether or not my child has retinitis pigmentosa?
- Does this genetic condition inevitably lead to blindness?
- What factors affect the rate at which this disorder progresses?
- What information can a genetic counselor provide about retinitis pigmentosa?

worsen. The symptoms may be similar to RP, but occur in the reverse order.

There are a few syndromes that involve RP. These include Usher syndrome and Bardet-Biedl syndrome. Usher syndrome is a group of recessive conditions that combine RP with deafness of varying degrees. Bardet-Biedl syndrome is a group of recessive conditions that combine RP with extra fingers and toes, mental delays, obesity, genital abnormalities, kidney abnormalities, and other medical complications. Genetic blood testing is available for some forms of Usher and Bardet-Biedl syndromes.

Genetic testing from a blood sample is available for some types of nonsyndromic RP on a clinical basis. In these cases, an abnormal result would identify a mutation (or mutations) in the gene causing RP for that individual. Other at-risk family members can sometimes be offered genetic testing once a mutation is identified in a family. In some cases, prenatal testing is available through an amniocentesis procedure. All genetic testing should be accompanied by careful genetic counseling.

Treatment and management

There is no cure for RP, or known way to stop the disease progression altogether. However, some things can help maintain good retinal function and health.

It is felt that a diet rich in leafy green vegetables and fish may be good for the retina. In addition, certain fish contain omega-3 fatty acids, such as docosahexaenoic acid (DHA) that is naturally found in the retina in very high concentrations. Eating a diet of fish like salmon, tuna, mackerel, or whitefish twice a week should naturally provide good DHA levels. Otherwise, good fish oil capsules containing DHA and other omega fatty acids can be obtained with a prescription or purchased at specialty health stores.

Multivitamins containing vitamins A, E, and C may be useful. These have antioxidant properties, which may be protective for the eyes. However, large doses of certain vitamins may be toxic, and affected individuals should speak to their doctors before taking supplements.

Protecting the eyes from harmful ultraviolet rays is essential to cone cell health. People with RP should wear good sunglasses outdoors and especially when over water or near snow on a bright, sunny day.

Smoking has been associated with deteriorating retinal health. Even quitting smoking late in life can make a positive impact on eye health.

PSCs do not usually severely impact the vision of those with RP. However, in some cases an ophthalmologist can remove the eye's lens and replace it with an artificial one to remove the cataract.

Low vision aids can be helpful for those in school or at work. Binocular lens and magnifying screens, large-print reading materials, closed-circuit television, special eyeglass lenses, and other tools can be helpful and are often available from organizations supporting those with vision loss.

Living with a chronic vision problem makes a significant impact on a person's life and family. It is often helpful for families to have a social worker connect them to helpful resources. Others may find genetic counseling, psychotherapy, or meeting other individuals with RP through support groups helpful.

Prognosis

Life expectancy is normal in RP. It eventually leads to serious visual impairment or blindness. The more severe forms will lead to blindness sooner than the milder forms, but each person's experience with the condition is unique and impossible to predict. Research and future treatments continue to offer hope for those with RP.

Retinoblastoma

Definition

Retinoblastoma is a rare cancer affecting the retina of one or both eyes. It occurs mainly in children under the age of five. The retina is the part of the eye that captures the images of the outside world and transfers these images to the brain. Most cases of retinoblastoma result when both copies of the RB1 gene, or less commonly the MYCN gene, have a pathogenic variant (mutation).

Retinoblastoma is a rare cancer affecting one or both eyes, most often in young children. (Custom Medical Stock)

In some case *RB1* gene variants can be passed down in families.

Description

Retinoblastoma accounts for about 4% of all cancers in children younger than age 15. Sixty percent of people with retinoblastoma have unilateral retinoblastoma, which affects only one eye. Unilateral retinoblastoma is usually diagnosed at age two. Forty percent of cases are bilateral, affecting both eyes, and these are usually diagnosed at 15 months.

Many of the early symptoms of retinoblastoma, such as intermittent pain of the eye, inflammation of the eye, and poor vision, are often overlooked. It is often a parent who first notices a whitish-appearing pupil (leukocoria), which leads to the diagnosis of retinoblastoma. If retinoblastoma is detected early enough, treatment such as surgery or radiation can result in a 95% cure and survival rate. If left untreated, retinoblastoma cancer cells can spread to other areas of the body, including the bone marrow.

Genetic profile

In order for cancer to develop, multiple genes in a retinal cell need to change (mutate). In some cases, the change produces a variant (mutation) in a tumor-suppressor gene. A tumor suppressor contains instructions for a protein that normally helps stop cancer from starting. Tumor suppressor proteins work by regulating cell growth and preventing cells from dividing too quickly or abnormally. In other cases, the variant activates a gene that causes the cell to grow out of control (oncogene). Variants in these genes cause the cells in

the retina to divide uncontrollably and form cancerous tumors.

The most important gene that is involved in retinoblastoma is *RB1*, which is a tumor suppressor gene. For most people with this condition, the retinoblastoma starts only if both copies of the *RB1* gene have variants in at least one cell. In 1.5% of individuals with isolated unilateral retinoblastoma, there are no variants in their *RB1* gene. Instead, they have variants in both copies of their *MYCN* oncogene.

About one in three people with retinoblastoma are born with a variant in the *RB1* gene in every cell of their body. This is called germline retinoblastoma. People with germline retinoblastoma have a 50% chance of passing it on to their children. For three out of four (75%) children, this germline variant happened early in fetal development (de novo). The other one out of four (25%) inherited it from one of their parents.

Having germline retinoblastoma increases the risk of cancer, because a variant only has to happen in the other *RB1* gene in one cell for cancer to develop. What causes a variant in the other copy of the gene is not known, but in some cases, DNA-damaging agents, such as radiation, tobacco, or UV light, might be responsible.

In some cases, the variant can look de novo but actually have come from a variant that was in the sperm or egg. This is called germline mosaicism. In those cases, some of the eggs from the mother or some of the sperm from the father have a variant in one copy of their *RB1* gene. A person with germline mosaicism has less than a 1% chance (approximately 0.08%) of having another child with retinoblastoma. Although a low risk, this is

Retinoblastoma: pedigree analysis chart (Gale)

Retinoblastoma

Sporadic

Retinoblastoma: pedigree analysis chart (Gale)

still 200 to 500 times higher than the general population's risk. If the germline variation is inherited from a parent who also has a germline variant, then the risk to other siblings is 50%

In germline retinoblastoma, the *RB1* gene variant is inherited in an autosomal dominant pattern, which means that a variant in only one copy of the *RB1* gene is sufficient to increase cancer risk. The retinal cancer does not happen unless the other copy acquires a variant in at least one retinal cell, which usually happens after the child is born. A person with bilateral retinoblastoma usually has germline retinoblastoma. But individuals with germline retinoblastoma can also have unilateral cancer. Those with germline retinoblastoma are also at an increased risk for other types of cancer.

The chance that someone with germline retinoblastoma will develop retinal cancer depends on the type of variant that they have. Most people with germline retinoblastoma have a null variant that produces no normal protein. They have a greater than 99% chance of developing retinal cancer. Fewer than one in ten (10%) people with germline retinoblastoma have a variant where their risk of cancer is only about 25(10%). In some rare cases, the risk of getting developing cancer is higher if the variant comes from the father rather than the mother.

Retinoblastoma can also be sporadic, which means that the child is born with two normal copies of the *RB1* gene and the *MYCN* gene. In sporadic retinoblastoma, both copies of either the *RB1* or *MYCN* gene acquire variants. What causes these variants is not known, although in some cases DNA-damaging agents such as radiation, tobacco, or UV light might be responsible. Retinoblastoma caused by variants in the *MYCN* gene are always sporadic. In sporadic retinoblastoma,

usually only one eye is affected. Genetic testing can usually determine whether the retinoblastoma is germline or sporadic.

Some people have mosaic retinoblastoma, meaning that they have a variant in their *RB1* gene in only some of the cells of their body, which can increase their risk of retinoblastoma. The degree of risk depends on how many cells have the variant. It can be difficult to diagnose mosaic retinoblastoma.

Approximately 5% to 8% of people with retinoblastoma have a piece missing (deletion) of chromosome 13 that contains the *RB1* gene. Because this chromosomal deletion includes other genes, affected children usually display other symptoms, such as intellectual disability, slow growth, and distinctive abnormal facial features.

Demographics

Retinoblastoma is the most common type of eye cancer in children. It accounts for about 4% of all cancers in children younger than age 15. It occurs worldwide in approximately one in 15,000–20,000 births. Approximately 250–300 children and adolescents are diagnosed with retinoblastomas each year in the United States. Most retinoblastoma cases occur among young children, with almost 63% of all retinoblastomas occurring before the age of two, and 95% occurring before the age of five. Rates of retinoblastoma are essentially equal among males and females and among different races and ethnicities.

Signs and symptoms

Since the successful management of retinoblastoma depends on detecting it early, recognition of the

signs and symptoms of the condition is critical, especially for primary care physicians, who are often the first medical personnel to see infants or children with retinoblastoma.

There are many ways that retinoblastoma can present itself in infants and children. More than half of all patients with the condition will have a white pupil reflex called leukocoria. In healthy infants and children, their pupils will appear black or, when photographed, red. However, patients with retinoblastoma will often have a pupil that appears gray or white.

The second most commonly presenting sign of retinoblastoma, occurring about 25% of the time, is a crossed eye, a medical condition referred to as strabismus. The child's eye may appear to be looking out toward the ear, called *exotropia*, or inward toward the nose, called *esotropia*. It should be noted that 3% to 4% of all American children present with some form of strabismus, but not all of these children have retinoblastoma. However, since 25% of children with retinoblastoma have strabismus, any child with this condition should have a detailed eye exam to rule out retinoblastoma.

While leukocoria and strabismus are the two most commonly presenting signs of retinoblastoma, there are other ways the condition may present itself. Other symptoms may include a red, painful eye, poor vision, orbital cellulitis (inflammation of the skin and tissue around the eye), and amblyopia, or "lazy eye." Heterochromia, a difference in coloration of the irises (the colored part in the

Illustration of a retinoblastoma, a rare cancerous tumor in the retina of eye. (Stocktrek Images/Science Source)

KEY TERMS

Esotropia—A form of strabismus in which one or both eyes turns inward.

Exotropia—A form of strabismus where the eyes are deviated outward.

Germline retinoblastoma—A type of retinoblastoma where all cells of the body have a variant in one copy of the *RB1* gene. This can be inherited or result early in the development of the embryo.

Leukocoria—An abnormal white reflection from the retina.

Mosaic retinoblastoma—A type of retinoblastoma where a variant in one copy of the *RB1* gene is found in only some cells of the body.

Pathogenic variant—A variation in a gene that causes problems with the protein the gene produces.

Retina—Multilayered sensory tissue that lines the back of the eye. It contains millions of photoreceptors that capture light rays and convert them into electrical impulses. These impulses travel along the optic nerve to the brain, where they are turned into images.

Sporadic retinoblastoma—A type of retinoblastoma where the cancer-causing gene variants happen in a retinal cell after birth and are not inherited.

Strabismus—A condition in which the eyes are not properly aligned with each other.

center of the eye surrounding the pupil), may also be the first sign of retinoblastoma.

Other Symptoms of Germline Retinoblastoma

People with germline retinoblastoma are at increased risk for benign (non-cancerous) retinal tumors called retinomas. Retinomas sometimes develop into cancer, but other times they stay benign. These individuals are at slightly increased risk for tumors in retinal-like tissue in the pineal gland of the brain. These tumors are rare and usually fatal.

People with germline retinoblastoma are also at increased risk for tumors in other parts of the body, such as the bone, muscles, and skin. These tumors usually develop in adolescence or adulthood. The chance of developing one of these tumors is 50% in people with germline retinoblastoma who also have had radiation

therapy. Even those who have not had radiation treatment have a high lifetime risk of cancer.

Diagnosis

The diagnosis of retinoblastoma is frequently made by the parents of an infant or child with the condition. Often, the parents will tell the physician that they have noticed that their child's eye looks "white," or that the child's eye or eyes seem to drift to one side or the other.

When a child is born into a family with a history of retinoblastoma, diagnosis of the condition can often be made before the baby leaves the hospital, by an ophthalmologist. If there is no family history, and the initial diagnosis is made by the parents or family physician, then the child can be sent to an ophthalmologist for a more thorough eye exam.

To examine a child for retinoblastoma, dilating drops are placed in both eyes to dilate (enlarge) the pupils and allow the ophthalmologist to view the retina. If a tumor is seen or suspected, an ultrasound examination, which uses sound waves to penetrate and outline structures in the eye, is used to confirm the presence of a tumor. Computed tomography (CT) scans use computers to take very detailed pictures of the inside of the body and can be used to see whether there are tumors in other parts of the body.

Genetic Testing

Since the gene responsible for retinoblastoma has been identified, genetic testing is available. Individuals who are most likely to have germline retinoblastoma are those with bilateral retinoblastoma, retinoblastoma in the family, or those with unilateral retinoblastoma with multiple tumors. They should all have blood testing for variants in the *RB1* gene.

People with unilateral retinoblastoma who have only one tumor and no family history of the disease can first have testing of their tumor tissue. If an *RB1* variant is found, then a blood test looking for this variant should be done. If no tumor tissue is available, then they should have blood testing for *RB1* variants.

Treatment and management

Treatment options for retinoblastoma have significantly increased over the past twenty years. The earliest form of treatment for retinoblastoma was *enucleation*, the removal of the major portion of the affected eye. This procedure led to total loss of vision in that eye. While enucleation is still used, especially when the tumor is very large, newer and more sophisticated treatments have emerged that offer the chance to save at least some vision in the affected eye.

QUESTIONS TO ASK YOUR DOCTOR

- My child has just been diagnosed with unilateral retinoblastoma. What is the long-term prognosis for the disorder likely to be?
- What kind of ongoing treatment does my child need to deal with this disorder?
- What are the differences in symptoms and prognosis between unilateral and bilateral retinoblastoma?
- Are there surgical treatments for retinoblastoma?

Lasers can be used in a treatment known as photocoagulation. This treatment is best used when the tumor is small and confined to the retina. The laser is actually used to burn and destroy blood vessels that feed the tumor rather than directly on the tumor itself. The treatment can be repeated once or twice, and in some studies complete remission of the retinoblastoma has been achieved in 70% of patients.

Another treatment that works well with tumors that are confined to the retina is cryotherapy. It may be used as either the primary mode of treatment or in conjunction with other treatment modalities. Like photocoagulation, cryotherapy has its highest success rates with smaller tumors. Unlike photocoagulation, cryotherapy uses extreme cold to destroy the tumor itself.

Thermotherapy uses heat generated from ultrasound or microwaves to destroy the retinoblastoma tumor. While thermotherapy works well on its own with small tumors, it is even more effective when used with chemotherapy or radiation therapy, which are thought to make the tumor more susceptible to the heat generated by thermotherapy.

The use of radiation treatment is not recommended, as it can increase the risk of future tumors. Of patients who receive external beam radiation, 35% develop another retinoblastoma within a 30-year time frame. It is, therefore, only used if treatment, such as cryotherapy or photocoagulation, fails or cannot be used due to large tumor size. While radiation is applied directly to the tumor, with careful application, the eye itself can be saved from destruction in about 75% of patients.

Probably the most significant advancement in the treatment and management of retinoblastoma has come about in the use of chemotherapy. While in the past, chemotherapy was only used to treat patients whose tumors had spread outside the eye, newer chemotherapy agents,

such as carboplatin and etoposide, along with older agents such as vincristine, are being used with significant success to treat tumors that are confined to the eye. Using these chemotherapeutic agents, it has been shown that tumors typically decrease in size 30% to 45% of the time. This then allows more conservative and eye-sparing therapy, such as cryotherapy and photocoagulation, to be used much more effectively. New chemotherapies that precisely target the tumor, while sparing vision and reducing side effects, are being developed. New criteria such as the RB-RECIST criteria will help to better evaluate the efficacy of chemotherapeutic agents targeting retinoblastoma in clinical trials.

Monitoring

Children with germline RB1 variants should have eye examinations under anesthesia every three to four weeks until they are six months old, and then every three to six months until age three. After that, they should have yearly exams until age seven, and then exams every two years for the rest of their life. DNA-damaging agents such as radiation, tobacco, and UV light should be avoided when possible.

Even people who do not appear to have germline retinoblastoma, should have regular clinical examination of the eyes, including ultrasound. This is because they could have mosaic retinoblastoma.

Prognosis

The prognosis for the vast majority of patients with retinoblastoma is excellent. In the United States, over 95% of children with retinoblastoma survive and lead healthy, productive lives.

Children who have unilateral retinoblastoma have at least one normal eye and can lead normal childhood lives, and even drive cars as they get older. The majority of children with bilateral retinoblastoma retain some vision in one eye, and sometimes in both eyes. However, all children who are affected with bilateral retinoblastoma and 15% of children with familial unilateral retinoblastoma have a higher risk of developing other cancers throughout their lives. Therefore, children in these categories need to have regular medical checkups throughout their lives to watch for any signs of secondary cancers in areas such as bone, muscle, skin, and brain.

Rett syndrome

Definition

Rett syndrome is a progressive neurological disorder seen almost exclusively in females. The most common symptoms are decreased speech, intellectual disability, severe lack of coordination, small head size, and unusual hand movements.

Description

Dr. Andreas Rett first reported females with the symptoms of Rett syndrome in 1966. Females with this X-linked dominant genetic condition are healthy and of average size at birth. During infancy, head growth is abnormally slow and microcephaly (small head size) develops. Babies with Rett syndrome initially have normal development. At approximately one year of age, development slows and eventually stops. Patients with Rett syndrome develop autistic features. Involuntary hand movements are a classic feature of Rett syndrome.

Females with Rett syndrome may also develop seizures, curvature of the spine (scoliosis), irregular breathing patterns, swallowing problems, constipation, and

difficulties walking. Some females with Rett syndrome are unable to walk. There is currently no cure for Rett syndrome. Most girls with Rett syndrome live until adulthood. The gene responsible for Rett syndrome has been identified and genetic testing is available.

Genetic profile

Rett syndrome is an X-linked condition. This means that the mutation (genetic change) responsible for Rett syndrome affects a gene located on the X chromosome. The affected gene is the methyl CpG-binding protein 2 (*MECP2*) gene. This gene makes a protein that regulates other genes. When there is a mutation in *MECP2*, the protein it makes does not work properly. This is thought to prevent normal neuron (nerve cell) development.

Rett syndrome is considered to be X-linked dominant in nature. Males have one X chromosome and one Y chromosome. Females have two X chromosomes. Males with a mutation in their *MECP2* gene typically die as infants or are miscarried before birth. Rett syndrome is usually considered fatal in males because the Y

Maryjane Luntz, a child with Rett syndrome, works on her hand-eye coordination by trying to pop bubbles. The disorder leads to developmental reversals. (ZUMA Press, Inc./Alamy)

chromosome cannot compensate for the *MECP2* mutation on the X chromosome. Females with a mutation in the *MECP2* gene develop Rett syndrome, but the presence of the second X chromosome in females carrying a normal *MECP2* gene enables them to survive.

The severity of the syndrome in females is related to the type of mutation in the *MECP2* gene and the activity of the X chromosomes. Normally, both X chromosomes have the same activity. However, the activity can be unequal. If the X chromosome with the mutation in the *MECP2* gene is more active than the X chromosome without the mutation, the female is more severely affected. The reverse is also true. If the X chromosome without the mutation is more active than the X chromosome with the mutation, the female is less severely affected.

If a woman has a mutation in her *MECP2* gene, she has a 50% risk with any pregnancy to pass on her X chromosome with the mutation. However, it is uncommon for women with Rett syndrome to have children due to the severity of the disorder.

Demographics

The incidence of Rett syndrome is estimated to be 1 in 8,500 females. It is seen almost exclusively in females. The vast majority of cases of Rett syndrome are sporadic in nature. Therefore, the risk of a family having more than one affected daughter is typically very low.

Signs and symptoms

Infants with Rett syndrome typically have normal size at birth. They develop normally until approximately 6–18 months of age. Development then slows, eventually stops, and soon regresses. Affected individuals are unable to do things they were once able to do. Girls with Rett syndrome lose the ability to speak, become uninterested in interacting with others, and stop voluntarily using their hands. The loss of language and eye contact causes girls with Rett syndrome to appear to be autistic. Between one and three years of age, girls with Rett syndrome develop the unusual hand movements that are associated with the disease. Patients wring their hands, clap their hands, and put their hands in their mouth involuntarily. Some patients with Rett syndrome also lose the ability to walk. If the ability to walk is maintained, the gait is very ataxic (uncoordinated, clumsy).

By preschool age, the developmental deterioration of girls with Rett syndrome stops, but they continue to have lack of speech, inability to understand language, poor eye contact, intellectual disability, ataxia, and apraxia (inability to make purposeful movements). Other common symptoms associated with Rett syndrome include

KEY TERMS

Apraxia—Impairment of the ability to make purposeful movements, but not paralysis or loss of sensation.

Ataxia—A deficiency of muscular coordination, especially when voluntary movements are attempted, such as grasping or walking.

Autism—A syndrome characterized by a lack of responsiveness to other people or outside stimulus. Often in conjunction with a severe impairment of verbal and nonverbal communication skills.

Microcephaly—An abnormally small head.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and can be transmitted to offspring.

Neuron—The fundamental nerve cell that conducts impulses across the cell membrane.

Scoliosis—An abnormal, side-to-side curvature of the spine.

Spasticity—Increased muscle tone, or stiffness, which leads to uncontrolled, awkward movements.

seizures, constipation, irregular breathing, scoliosis, swallowing problems, teeth grinding, sleep disturbances, and poor circulation. As patients with Rett syndrome get older, their ability to move decreases and spasticity (rigidity of muscles) increases.

Diagnosis

The diagnosis of Rett syndrome is made when the majority of the symptoms associated with the disease are present. If a physician suspects an individual has Rett syndrome, DNA testing is recommended. Approximately 75% of patients with Rett syndrome have a mutation in the *MECP2* gene. DNA testing can be performed on a blood sample, or other types of tissue from the body. If a mutation is found in the *MECP2* gene, the diagnosis of Rett syndrome is confirmed.

Treatment and management

Currently there is no cure for Rett syndrome. Treatment of patients with Rett syndrome focuses on the symptoms present. Treatment may include medications that inhibit seizures, reduce spasticity, and prevent sleep disturbances. Nutrition is monitored in females with Rett

QUESTIONS TO ASK YOUR DOCTOR

- What are the typical signs and symptoms of Rett syndrome?
- Why does this disorder occur almost exclusively among females?
- Given that we already have one daughter with Rett syndrome, what is the probability of having a second child with the same genetic disorder?
- What is the prognosis for our daughter with Rett syndrome, and on what information do you base that prognosis?

syndrome due to their small stature and the constipation associated with the disorder.

Prognosis

In the absence of severe medical problems, most patients with Rett syndrome live into adulthood.

Rheumatoid arthritis

Definition

Rheumatoid arthritis (RA) is a chronic inflammatory disease affecting the joints, most often in the hands and feet. It results in swelling; stiffness; pain; and sometimes joint, bone, and cartilage destruction.

Description

Rheumatoid arthritis (RA) belongs to a group of diseases called autoimmune disorders that affects joints. In RA, the immune system, the function of which is to protect the body, produces antibodies that attack the soft tissues lining the joints. Eventually the cartilage, bone, and ligaments of the joint deteriorate, causing deformity, instability, and scarring within the joint. The rate at which the joints deteriorate varies with the individual. A number of risk factors including genetic predisposition, gender, and unspecified environmental factors may put a person at risk for developing the disease, as well as influence the pattern of the disease.

As with other forms of arthritis, RA involves inflammation of the joints. A membrane called the synovium lines each of the body's movable joints. In RA, white blood cells that normally protect against invaders such as bacteria and viruses move from the bloodstream into the synovium, causing inflammation to the synovial membrane. This inflammation is called synovitis and results in the release of proteins that over time cause thickening of the synovium. These proteins can also damage cartilage, bone, tendons, and ligaments. Gradually the joint loses its shape and alignment, and eventually may be destroyed.

Genetic profile

RA is a genetically complex disease. Studies in monozygotic (identical) and dizygotic (fraternal) twins indicate that genetic factors are involved in acquiring the susceptibility or tendency to RA rather than the disease itself. People with certain human leukocyte antigen (HLA) genes—specifically, the genetic marker called

HLA-DR4 (the *DR4* refers to the specific antigen)—are more likely to develop the disease than those without the genes. However, people without this antigen can develop the disease as well.

The *HLA-DR4* marker is found in white blood cells and plays a role in helping the body distinguish between its own cells and foreign invaders. In addition, these genes help predict the severity of the disease and how effectively the disease responds to treatment. The mechanism by which HLA alleles (HLA genetic variations) affect disease risk is still under investigation.

In one study, French scientists found 63 genes that appear to be linked to the development of RA. The group studied and compared the expression of 5,200 genes in the synovial fluid of a group of patients with RA and another group with osteoarthritis. The researchers found 48 known and 15 unknown genes that were either overexpressed or underexpressed in RA patients compared with osteoarthritis patients. Two of the novel genes were located on chromosome 6, at the p21 region, which is an area already linked to inflammatory disease. Four other genes were located on the X chromosome.

RA is three times more common in smokers than in nonsmokers, particularly in men. Vitamin D deficiency has also been linked to RA prevalence. While the link is

not well understood and some of the data are conflicting, it is thought that because the active metabolite 1,25-dihydroxyvitamin D3 (1,25D) indirectly affects bone metabolism, a deficiency in vitamin D may also contribute to RA.

Demographics

Rheumatoid arthritis affects approximately 1% of the worldwide population. Although some people have a mild form of RA, 70% eventually develop chronic problems and 15% have a severe, crippling form of the disease.

The disease occurs in all races and countries, and although RA affects women two to three times more often than men, men tend to be affected more severely by it. The onset of RA most commonly occurs between the ages of 25 and 50, but children and adolescents as well as the elderly may also be affected. When the disease occurs in children it is referred to as juvenile RA.

Signs and symptoms

The course of RA can vary with each case; some people may have mild symptoms, occasional flare-ups, and long periods without disease (remission), or they

A woman's hands affected by rheumatoid arthritis. (Hriana/Shutterstock)

may have RA that progresses steadily at different rates. The disease may begin suddenly with many joints becoming inflamed simultaneously. Most often, however, RA begins subtly and gradually affects different joints. Usually the inflammation is symmetric with joints on both sides of the body affected. Typically the small joints in the hands, feet, wrists, elbows, and ankles become inflamed first. The inflamed joints are usually painful and often stiff, especially just after awakening or after prolonged inactivity. This stiffness generally lasts for at least 30 minutes but can also last much longer. Some people feel tired and weak, especially in the early afternoon. In addition, RA may produce a low-grade fever.

Affected joints enlarge because of swelling of the soft tissue and can quickly become deformed. Joints may freeze in one position and cannot bend or open fully. The fingers may tend to dislocate from their normal position toward the little finger on each hand, causing tendons in the fingers to slip out of place.

Swollen wrists can pinch a nerve and result in numbness or tingling due to carpal tunnel syndrome. Cysts can develop behind affected knees and rupture, causing pain and swelling in the lower legs. Up to 30% of people with RA have hard bumps (rheumatoid nodules) just under the skin, usually near sites of pressure. Common areas for rheumatoid nodules to develop are on the back of the forearm near the elbow.

In rare cases, RA causes an inflammation of blood vessels called vasculitis; this condition reduces the blood supply to tissues and may cause nerve damage or leg sores (ulcers) that may become infected. Inflammation of the membranes covering the lungs (pleura) or of the sac surrounding the heart (pericardium), or inflammation and scarring of the lungs, can lead to chest pain and shortness of breath. Some people develop swollen lymph nodes, dry eyes or mouth, or red, painful eyes as a result of inflammation associated with RA.

Diagnosis

In addition to the important characteristic pattern of symptoms, many tests may be used to support the diagnosis.

Laboratory tests may include rheumatoid factor, white blood cell count, anemia, erythrocyte sedimentation rate (ESR or sed rate), and C-reactive protein, which is a marker for inflammation.

Many people with RA have certain characteristic antibodies in their blood that are present in 70% of people with RA. The rheumatoid factor antibody occurs in RA and several other diseases, such as hepatitis and other infections. Some people even have rheumatoid factor in their blood without any evidence of disease. A higher level of rheumatoid factor in the blood usually results in

X-ray of a patient's hand with severe rheumatoid arthritis in all of the fingers. (Zephyr/Science Photo Library/Alamy)

a more severe RA and a poorer prognosis, and the level may decrease when joints are less inflamed.

Most people who suffer from RA have mild anemia (an insufficient number of red blood cells). Rarely the white blood cell count becomes abnormally low but when a person with RA has a low white blood cell count and an enlarged spleen, the disorder is called Felty's syndrome.

Nine out of ten people with RA have an elevated sed rate, which depends on certain proteins present in the blood. An elevated sed rate suggests that active inflammation is present; however, this test alone cannot identify the cause of the inflammation. Doctors may monitor the sed rate when symptoms are mild to help determine whether RA is still active.

A needle biopsy may be recommended to examine joint fluid or a tissue sample from rheumatoid nodules.

Characteristic changes in the joints may be monitored through the use of x-rays.

Treatment and management

Treatments for RA have improved in recent years, although most treatments involve medications and in some cases surgical procedures may be necessary.

Medications for RA can relieve its symptoms and slow or halt its progression. Nonsteroidal anti-inflammatory drugs (NSAIDs) help to alleviate both pain and inflammation if taken on a regular basis. These drugs are available without a prescription and include aspirin, ibuprofen, and naproxen. These medications are available at higher dosages by prescription.

Taking NSAIDs on a regular basis can lead to adverse side effects, such as indigestion and stomach bleeding. Other potential harmful side effects may include damage to the liver and kidneys, ringing in the ears (tinnitus), fluid retention, and hypertension (high blood pressure).

Initially, it was thought that COX-2 inhibitors, another class of NSAIDs, were less damaging to the stomach than the traditional NSAIDs. It was believed that NSAIDs work against two versions of the COX enzyme present in the body: COX-1 and COX-2. However, there is increasing evidence to suggest that by suppressing COX-1, which is the enzyme responsible for protecting the stomach lining, NSAIDs may cause stomach and other problems. Unlike other NSAIDs, COX-2 inhibitors suppress only COX-2, the enzyme involved in inflammation. Celecoxib (Celebrex), which is one of the few COX-2 inhibitors still on the market in the United States, suppresses an enzyme called cyclooxygenase (COX) that is active in joint inflammation.

Side effects of COX-2 inhibitors may include fluid retention and causing or exacerbating high blood pressure. Furthermore, this class of drugs has been linked to an increased risk of heart attack and stroke. These are reasons why Merck Pharmaceuticals chose to remove its COX-2 inhibitor rofecoxib (Vioxx) from the worldwide market in September 2004. About 1.3 million people in the United States and about 700,000 abroad were using the drug. In April 2005, the COX-2 inhibitor valdecoxib (Bextra) manufactured by Pfizer was voluntarily removed from the market at the request of the FDA due to the reported potential risks of heart attack, stroke, and potentially life-threatening skin reactions that were greater than its benefits. The FDA also announced new label requirements for both prescription and nonprescription NSAIDs. Prescription labels for COX-2 inhibitors like celecoxib were required to carry a “black box warning” that stressed the life-threatening effects associated with the drug.

In December 2004, the FDA issued a Public Health Advisory recommending limited use of COX-2 inhibitors. The guidelines warned patients against the use of COX-2 inhibitors if they were at high risk of gastrointestinal bleeding and had a history of intolerance to certain NSAIDs. The risks commonly associated with NSAIDs should be taken into account for each patient as

KEY TERMS

Antibodies—Protein molecules the body produces to fight infection.

Autoimmune disorder—Disorder occurring when the body's tissues are attacked by its own immune system.

Cyclooxygenase-2 (COX-2) inhibitors—Anti-inflammatory drugs that work by blocking the COX-2 enzyme, which plays a role in the inflammatory process. COX-2 inhibitors do not block the COX-1 enzyme, which helps protect the digestive tract.

Inflammation—A localized protective response elicited by injury or destruction of tissues and characterized by pain, heat, redness, swelling, or loss of function.

Tumor necrosis factor (TNF)—A protein that plays an early and major role in the rheumatic disease process.

individuals can respond differently to the medication. Consumers are advised that all nonprescription pain relievers, including NSAIDs, should be used exactly as specified on the label. If NSAIDs are needed for more than 10 days, the FDA suggests that a doctor be consulted.

The FDA's actions differ from the recommendations of an FDA expert advisory panel, which, in February 2005, voted in favor of allowing COX-2 inhibitors celecoxib and valdecoxib to remain available. The panel also voted to allow rofecoxib back on the market but under strict conditions.

Corticosteroids like prednisone (Deltasone) and methylprednisolone (Medrol) reduce inflammation and pain, and slow the progression of joint damage and destruction associated with RA. In the short term, corticosteroids alleviate pain significantly but when used for many months or years these drugs tend to lose their efficacy and cause serious side effects that may include bruising, thinning of bones, cataracts, weight gain, and diabetes. Doctors often prescribe corticosteroids to alleviate acute symptoms with the goal of gradually tapering off the medication when the patient's pain decreases.

Physicians prescribe disease-modifying antirheumatic drugs (DMARDs) to limit the amount of joint damage that occurs in RA. Taking these drugs during the early stages in the development of RA is especially important in an attempt to slow disease progression and save the joints and other tissues from permanent damage.

Because many of these drugs act slowly it may take weeks to months to detect any benefit. Typically DMARDs are used in combination with an NSAID or a corticosteroid. Although the NSAIDs or corticosteroids alleviate any immediate symptoms and limits inflammation, the DMARDs act directly on the disease. Commonly used DMARDs include hydroxychloroquine (Plaquenil), the gold compound auranofin (Ridaura), sulfasalazine (Azulfidine), and minocycline (Dynacin and Minocin). Additional forms of DMARDs include immunosuppressants and tumor necrosis factor (TNF) blockers.

Immunosuppressants are used to suppress the immune system, which is overactive in RA. In addition, some of these drugs attack and destroy cells associated with the disease. Some of the commonly used immunosuppressants include methotrexate (Rheumatrex), leflunomide (Arava), azathioprine (Imuran), cyclosporine (Neoral, Sandimmune), and cyclophosphamide (Cytoxan). These medications may have potentially serious adverse side effects; for example, increased susceptibility to infection.

The TNFs are a class of DMARDs known as biologic response modifiers. TNF is a type of protein called a cytokine. Cytokines act as inflammatory agents in RA. TNF blockers target or block cytokine activity and can help reduce pain, morning stiffness, and tender or swollen joints, typically within one or two weeks after initiating treatment. There is evidence that TNF blockers may halt the progression of the disease. Often these medications are taken in combination with the immunosuppressant methotrexate. The TNF blockers approved for treatment of RA include etanercept (Enbrel), infliximab (Remicade), and adalimumab (Humira). These medications should not be taken if active infection is present because they inhibit the immune response.

Interleukin-1 receptor antagonist (IL-1RA) is a molecule that competes with the naturally occurring molecule interleukin-1 (IL-1) for the binding of the interleukin-1 receptor (IL-1R). IL-1RA is an inhibitor of inflammatory responses, where IL-1 promotes inflammation and occurs at high levels in people with RA or other types of inflammatory arthritis. As IL-1RA outcompetes IL-1 for binding of IL-1R, the inflammatory response is decreased. IL-1RA is a naturally occurring molecule but can also be produced synthetically as a treatment for inflammatory disease.

The first IL-1RA approved by the FDA for use in individuals with moderate to severe RA who have not responded adequately to conventional DMARD therapy is anakinra (Kineret). This drug may be used alone or in combination with methotrexate. Anakinra is administered as a daily self-injection. Some potential side effects

include injection-site reactions, decreased white blood cell counts, headache, and increased upper respiratory tract infections, especially in people with asthma or chronic obstructive pulmonary disease. If active infection is present, anakinra should not be used.

Some people with RA also experience symptoms of depression. The most common antidepressants used for RA pain and for sleep that is not restful are amitriptyline (Elavil), nortriptyline (Aventyl, Pamelor), and trazodone (Desyrel).

Although a combination of medication and self-care is the first course of action for RA, other methods are available in severe cases of the disease. The Prosorba column is a blood-filtering technique used to remove certain antibodies that contribute to pain and inflammation in the joints and muscles and is usually performed once a week for 12 weeks on an outpatient basis. Some of the side effects of this procedure include fatigue and a temporary increase in joint pain and swelling for the first few days after the treatment. The Prosorba column treatment is not recommended in combination with angiotensin-converting enzyme (ACE) inhibitors or if heart problems, high blood pressure, or blood-clotting problems are present.

Joint replacement surgery is an option chosen by many people with RA when less invasive methods or medications are not able to alleviate pain and deter joint destruction. Joint replacement surgery can often help restore joint function, reduce pain, or correct a deformity when joints are severely damaged. In some cases the entire joint may need to be replaced with a metal, ceramic, or plastic prosthesis. Surgery may also involve tightening or loosening tendons, fusing bones to reduce pain, or removing a portion of a diseased bone to improve mobility. The inflamed joint lining may also require removal (synovectomy).

Prognosis

In rare cases, RA resolves spontaneously; however, at least 1 out of 10 people with RA eventually becomes severely disabled.

Rhizomelic chondrodysplasia punctata

Definition

Rhizomelic chondrodysplasia punctata is a rare and severe inherited disease that affects brain development. The main features are limb shortening, bone and cartilage abnormalities that are visible on x-ray, abnormal facial appearance, severe intellectual disability, profound psychomotor retardation, and cataracts. Skeletal abnormalities can be seen prenatally, and most affected individuals die in infancy. No treatments are available.

Description

Rhizomelic chondrodysplasia punctata (RCDP) causes an abnormal protein that is localized to the peroxisome cells. The inside of the cell contains compartments called organelles that perform specific functions. Cells contain several peroxisome compartments that function in many metabolic processes, especially those involving lipids (fats) and hydrogen peroxide. RCDP is considered to be a peroxisomal disorder, as well as a metabolic disorder.

KEY TERMS

Anticoagulant—Drugs used to prevent blood clots.

Cell—The smallest living unit of the body, which group together to form tissues and help the body perform specific functions.

Differentiate—Specialized development to perform a particular function.

Gene—A building block of inheritance, which contains the instructions for the production of a particular protein and is made up of a molecular sequence found on a section of DNA. Each gene is found on a precise location on a chromosome.

Metabolism—The total combination of all of the chemical processes that occur within cells and tissues of a living body.

Plasmalogens—The fat molecules that are important components of cells and of the myelin sheath that protects nerve cells.

Protein—Important building blocks of the body composed of amino acids, involved in the formation of body structures and controlling the basic functions of the human body.

Psychomotor—Movement produced by action of the mind or will.

Chondrodysplasia punctata describes similar conditions to RCDP because they describe a feature that is present in all four conditions but that differ in cause, associated features, and inheritance patterns; however, the causes, features, and patterns of inheritance of the other chondrodysplasia punctata conditions are different from those of RCDP.

There are three types of RCDP that have similar features and can be distinguished by the mutations in the different genes that cause them. RCDP1 is the most common and is caused by mutations in the *PEX7* gene; RCDP2 is due to a mutation in *GNPAT*; and RCDP3 is caused by mutations in *AGPS*. All these genes function in the synthesis of lipids called plasmalogens, whose function is not well understood but are found in the membranes in cells throughout the body. It is not yet clear how the loss of plasmalogens leads to the symptoms seen in RCDP.

Genetic profile

Rhizomelic chondrodysplasia punctata is an autosomal recessive condition. This means that it occurs in both males and females and can affect people who have no family history of the condition. Humans have two copies

of every gene, one maternally and one paternally inherited. Autosomal recessive conditions occur when a person has two abnormal copies of the same gene. People who have one abnormal copy and one normal copy of a particular gene are unaffected and are considered to be carriers for that disorder. A person affected with RCDP has inherited two abnormal genes, one from each parent. The risk for carrier parents to have another affected child is 25% with each pregnancy.

In 1997, *PEX7* was identified as the gene that causes RCDP. Fifteen genes involved in the synthesis of peroxisomes have been identified in humans and are classified as *PEX* genes. The proteins they code for are called peroxins. Disorders caused by abnormalities of peroxin proteins are often called peroxisomal biogenesis disorders.

The *PEX7* gene codes for a peroxisomal component that helps transport other important proteins into the peroxisome. The proteins to be transported contain a signal, called peroxisome targeting sequence 2 (PTS2) that is recognized by the receptor on the peroxisome. When *PEX7* is abnormal, the receptor that normally recognizes and helps transport the PTS2 proteins is not functional, thus having a cascade effect on many other cellular processes.

Demographics

RCDP is quite rare, occurring in fewer than 1 in 100,000 births. The incidence of peroxisomal biogenesis disorders is approximately 1 in 50,000 births, with RCDP accounting for less than one-fifth of these.

Signs and symptoms

Rhizomelic refers to shortening of the bones near the center of the body (the bones of the thighs and upper arms more so than the bones of the forearms and lower legs). Chondro refers to cartilage and dysplasia to abnormal development. Punctata refers to specific abnormal spotting on the ends of bones near the hip, knee, elbow, and shoulder joints that can be seen on radiological studies. The spots represent unusually dense cartilage and are also called punctate calcifications. Other abnormalities include frozen joints (called contractures), abnormal facial features, cataracts, hearing loss, severe intellectual disability, and profound psychomotor retardation. People with RCDP may also have other bone abnormalities, small heads, coarse and sparse hair, and dry, red skin.

The proximal shortening of the bones causes short stature, which is apparent before birth. Growth after birth is stunted as well. The rhizomelic shortening is severe and occurs to the same degree on both sides of the body. Severe intellectual disability is defined as a level of cognitive deficits worse than those of typical Down

QUESTIONS TO ASK YOUR DOCTOR

- What is the meaning of the term “rhizomelic chondrodysplasia punctata”?
- What causes this disorder?
- Is there any cure for this disease or any treatment to slow its progress?
- How long does a child with rhizomelic chondrodysplasia punctata typically survive?

syndrome. Some researchers have described degeneration of brain tissue after birth but the reason for this is unclear; it may be due to toxic effects of excess phytanic acid. Due to the abnormal facial features, those with RCDP have been called “koala bear faces.” Facial features include a broad forehead and a saddle nose.

Not all people with RCDP present all of the typical symptoms, and because the spectrum of features in RCDP is variable, some are more mildly affected than is typical. These differences in severity appear to be associated with different mutations in the *PEX7* gene.

Diagnosis

Although the physical and radiographic features can raise suspicion of RCDP, laboratory testing is required for making an accurate diagnosis. People with RCDP have very specific biochemical abnormalities, due to the underlying defect in the peroxisome. The specific abnormalities are (1) deficient plasmalogen synthesis leading to very low plasmalogen levels in red blood cells, (2) inability to process (oxidize) phytanic acid leading to elevated levels of phytanic acid in the blood, and (3) an unprocessed form of peroxisomal thiolase. Phytanic acid levels are normal at birth and increase to at least 10 times the normal level by one year of age. Some experts recommend that additional studies be performed on cells obtained by skin biopsy to confirm the diagnosis.

The biochemical studies to diagnose RCDP can be performed prenatally on cells obtained by chorionic villus sampling (CVS) or amniocentesis. CVS is usually performed from 10–12 weeks of pregnancy and amniocentesis after 15 weeks of pregnancy. RCDP may also be suspected in a fetus based on ultrasound findings.

The features of RCDP are seen in many other conditions; for example, rhizomelic limb shortening is seen in dwarfism, and chondrodysplasia punctata is a symptom of many inherited conditions but can also be caused by

prenatal exposure to the anticoagulant drug Warfarin. Doctors who specialize in diagnosing rare genetic conditions use subtle differences between the symptoms of these conditions to narrow their search for the suspected diagnosis. Many peroxisomal disorders have abnormal very long-chain fatty acids (VLCFAs) but VLCFA levels are normal in RCDP.

RCDP is the only condition that is caused by abnormal *PEX7* gene. Genetic testing is one method to confirm the diagnosis. A doctor who specializes in medical genetics can determine whether this testing is available clinically.

Treatment and management

The only treatments for RCDP are supportive therapies that address symptoms. People with RCDP, especially those who are less severely affected benefit from symptomatic support of various specialties such as ophthalmology and physical therapy. Dietary restrictions or supplements have shown promise in the treatment of some peroxisomal disorders. A serious issue in the severe cases is that many of the abnormalities develop before birth and are irreversible. The multiple biochemical abnormalities of RCDP also complicate treatment efforts. Some treatments try to improve the function of the deficient metabolic process and, if they work, will probably benefit patients mildly affected with RCDP more so than those that are severely affected by the disease.

The underlying cause of the severe intellectual disability is not well understood, although some abnormalities of nerve tissue have been described and are implicated in contributing to this symptom. In many peroxisomal disorders similar to RCDP, the nerve tissue migrates abnormally before birth. This abnormal migration is not present in RCDP, suggesting that in RCDP the nerve tissue may not differentiate properly once it has migrated to the correct location in the body.

Prognosis

The prognosis for the typical individual with RCDP who is severely affected is death in infancy. Most affected infants die in the first two years of life; however, exceptions have been reported in the medical literature. Individuals who lived past the age of ten years have been reported. For atypical or mildly affected patients the prognosis is variable.

Scientists' understanding of peroxisomal disorder, and of the peroxisome itself, increased enormously, but developing effective treatments of RCDP is a great challenge. Increased awareness of RCDP is leading to more

accurate diagnoses and higher clinical suspicion. A correct diagnosis is critical in providing accurate recurrence, prognosis, and prenatal diagnosis information.

Rhodopsin

Definition

Rhodopsin is the visual pigment that "senses" light in the rod cells of the retina.

Description

Rhodopsin is found at the back of the eye, in the retina. The retina is the area of the eye that senses light, interprets that information, and transmits it to the brain for further interpretation. Two types of light-sensing cells are found in the retina: rods and cones. In a simplified explanation, rod cells are responsible for black and white vision, whereas cone cells are responsible for color vision. This is true as far as it goes, but there are many more differences between rods and cones.

In rod cells, rhodopsin is responsible for phototransduction, the process of turning light into chemical and electrical energy. Rhodopsin is responsible for

phototransduction in rod cells, but not in cone cells. Three different proteins, similar to rhodopsin, govern phototransduction in the cone cells. Each of these three phototransducers responds to a different color of light, which allows persons with normal color vision to see the entire color spectrum.

In order to understand more of the structure, function, and location of rhodopsin, a discussion of cells and cell membranes is necessary. Every human cell has a cell membrane that separates the environment inside the cell (intracellular environment) from the extracellular (outside the cell) environment. Cell membranes are made up of lipids, which are hydrophobic substances. Hydrophobic literally means fear of water. Oil is an example of a hydrophobic substance. If oil is added to water, the oil will separate itself from the water. Basically, the lipids in the cell membrane form a similar water-excluding ball, but the inside of the ball will contain water and other intracellular fluids. Each rhodopsin molecule crosses the cell membrane seven times, and each area of the protein in the cell membrane is called a transmembrane domain. These transmembrane domains (which are hydrophobic) dictate an interesting structure for rhodopsin. Imagine folding a hose seven times to hold it in your hand. The structure for rhodopsin is at least that complex. Rhodopsin has seven transmembrane domains because that structure is common to G proteins, and rhodopsin is a G protein. G proteins are generally involved in a biological cascade. A biological cascade is a system where a small initial input (like a brief flash of light) can result in a rather large output.

Rhodopsin is a combination of two different molecules: retinal and opsin. Retinal is a derivative of vitamin A, and opsin is a protein. When rhodopsin is not activated, retinal is in the 11-cis configuration. When light hits 11-cis retinal, it changes its shape to become all-trans retinal. This is the only light-sensitive step in vision (in the rod cells). What the configurations are called and what those names mean is not as important as the fact that this light-dependent change in conformation results in light being converted into chemical energy.

Once retinal reaches the all-trans conformation, opsin also changes its shape. The new opsin-retinal complex is called metarhodopsin II. Metarhodopsin II is a semistable complex that is the active form of rhodopsin. Metarhodopsin II, unlike the inactive rhodopsin, is able to bind a protein called transducin. Each metarhodopsin II can bind to many transducins (literally hundreds). These transducins then cause a decrease in cGMP concentration, and one transducin molecule can cause the breakdown of more than 1,000 cGMP per second. One can clearly see why the G protein cascades are excellent systems for amplifying a signal.

QUESTIONS TO ASK YOUR DOCTOR

- What is rhodopsin, and what is its function in the process of vision?
- What abnormalities in rhodopsin can lead to genetic disorders?
- How serious are these disorders?
- Are there treatments for genetic rhodopsin abnormalities?

Genetic profile

Mutations in rhodopsin can result in two different disorders—retinitis pigmentosa and congenital stationary night blindness. Retinitis pigmentosa (RP) affects about 1 in 3,000 persons living in the United States, and about 1.5 million persons worldwide. Many mutations, not just mutations of the rhodopsin gene, lead to RP. The disorder may be inherited in an X-linked recessive fashion in 8% of all cases, an autosomal dominant fashion in 19% of cases, or as an autosomal recessive disorder in 19% of all cases. In the rest of the cases (54%), the mutations do not follow classical genetic patterns of inheritance. Mutations in rhodopsin have been found to cause approximately 20% of the autosomal dominant form of RP. The rhodopsin gene is located at the 3q locus of the chromosome.

Patients with retinitis pigmentosa exhibit symptoms that include night blindness, abnormal pigment accumulation in the retina, and a progressive decrease in the visual fields. The patient's vision decreases from the outermost edges in. The age of onset of the disorder may be as young as six months, but most patients experience the first symptoms between ages 10 and 30. In RP, the patient's rod cells usually degenerate first, followed by a loss of cone cells.

Signs and symptoms

Symptoms may often present after a motor vehicle accident. Not only is the age of onset variable, but the severity of the disease is as well. Patients with the same mutation, even within the same family, exhibit differing severities of the disorder. Mutations in rhodopsin may also cause autosomal recessive cases of RP.

Congenital stationary night blindness (CSNB) is another disorder that can be caused by mutations in the rhodopsin gene. Patients with CSNB, as may be deduced from the name, experience night blindness. However, unlike RP, patients with CSNB do not

experience degeneration (death) of cells of the retina (rod and cone cells). Patients with CSNB are thought to have an overactive transducin molecule, which prevents their rods from functioning normally. A mutation in transducin that also causes CSNB supports this theory, since this transducin is also thought to be overly active.

Treatment and management

No effective treatment for RP exists. However, new treatments are being explored for RP. Experiments in rats have shown that rod cells can be affected by gene therapy. Although gene therapy has not been successfully demonstrated as of this printing, at least the hope now exists that eventually gene therapy may be applied to the problem of RP. Previously, addition of a new gene into a nondividing cell line had been thought to be technically insurmountable. Another experiment in rodents offers hope for those who have autosomal recessive RP. Rats with autosomal recessive RP have been successfully treated with retinal pigment transplantation, according to Columbia University's *Retinal Transplant* newsletter. This technique might prove promising in humans.

Prognosis

The prognosis for persons with RP is extremely variable. Persons with CSNB will experience night blindness throughout their lives.

Rieger syndrome

Definition

Rieger syndrome is a rare disorder characterized by absence and/or malformation of certain teeth, mild craniofacial (relating to the head and the face) abnormalities, and various eye abnormalities. The eye abnormalities, referred to as Rieger eye malformations, may be present separately or as a part of Rieger syndrome.

Description

First characterized by Herwigh Rieger, an Austrian ophthalmologist, in 1935, Rieger syndrome is a dominantly inherited disease. Disease expression is highly variable, including craniofacial, ocular, and dental malformations. Symptoms may also include myotonic dystrophy (a condition characterized by delay in the ability to relax muscles), umbilical abnormalities (abnormalities relating to where the umbilical cord attaches to a baby), and other defects. Psychomotor retardation, a slowing of the motor action directly proceeding from mental activity, occurs in some cases.

Rieger syndrome is also sometimes referred to as goniodysgenesis hypodontia, iridogoniodysgenesis with somatic anomalies, or RGS. It is a multiple congenital anomaly syndrome, a syndrome marked by multiple abnormalities at birth. Currently, there are two genetic types of Rieger syndrome identified. Type I results from a mutation on chromosome 4, and Type II from a mutation on chromosome 13.

Genetic profile

Rieger syndrome is inherited as an autosomal dominant disease. In autosomal dominant inheritance, a single abnormal gene on one of the autosomal chromosomes (one of the first 22 nonsex chromosomes) from either parent can cause the disease. One of the parents will have the disease (since it is dominant) and is the carrier. Only one parent needs to be a carrier in order for the child to inherit the disease. A child who has one parent with the disease has a 50% chance of also having the disease.

There is evidence that there is more than one genetic form of Rieger syndrome. The disease gene responsible for Rieger syndrome Type I is caused by mutations in the *RIEG1* gene, which is located on the long arm (q) of chromosome 4 (4q25-Q26).

Linkage studies have indicated that a second type of Rieger syndrome, type II, maps to the long arm of chromosome 13, at 13q14 (gene *RIEG2*).

Demographics

Rieger syndrome is very rare. Little is known in regard to the number of affected individuals or whether certain areas or ethnic groups are at a greater risk. Since the disease appears to be inherited in an autosomal dominant manner, meaning that it is transmitted on one of the nonsex chromosomes, males and females have an equal chance of acquiring the abnormal gene from their parents.

Signs and symptoms

The symptoms of Rieger syndrome are expressed variably. The main symptoms of Rieger syndrome are:

- Ocular malformations, called Rieger eye malformations, include underdeveloped iris, a small cornea (microcornea), an opaque ring around the outer edge of the cornea, adhesions (abnormal union of surfaces normally separate) in the front of the eye, and/or displacement of the pupil of the eye so that it is not centered.
- Dental abnormalities include a congenital condition causing a fewer number of teeth than normal (hypodontia); a condition in which a single tooth, pairs of teeth, or all the teeth are smaller than normal (microdontia) and/or cone-shaped.
- Craniofacial abnormalities include a protruding lower lip, a broad, flat bridge of the nose, and/or underdeveloped bones of the upper jaw (hypoplasia) causing the face to have a flat appearance.

Other conditions that have been found in some patients with Rieger syndrome are:

- Anal stenosis (a small anal opening).
- Failure of the skin around the navel to decrease in size after birth.
- Protrusion of intestine through a weakness in the abdominal wall around the navel (umbilical hernia).
- Glaucoma (increased pressure within the eyeball) may result from the ocular malformations associated with Rieger syndrome, including defects in the angle of the eye that is created by the iris and cornea (trabecula), the vein at the corner of the eye that drains the water in the eye into the bloodstream (Schlemm's canal), and the associated adhesions. Glaucoma can result in damage

KEY TERMS

Cornea—The transparent structure of the eye over the lens that is continuous with the sclera in forming the outermost, protective layer of the eye.

Craniofacial—Relating to or involving both the head and the face.

Hypoplasia—Incomplete or underdevelopment of a tissue or organ.

Iris—The colored part of the eye, containing pigment and muscle cells that contract and dilate the pupil.

Microcornea—Abnormal smallness of the cornea.

Microdontia—Small teeth.

Myotonia—The inability to normally relax a muscle after contracting or tightening it.

Myotonic dystrophy—A form of muscular dystrophy, also known as Steinert's condition, characterized by delay in the ability to relax muscles after forceful contraction and wasting of muscles, as well as other abnormalities.

Ocular—A broad term that refers to structure and function of the eye.

Oligodontia—The absence of one or more teeth.

Psychomotor—Movement produced by action of the mind or will.

Stenosis—The constricting or narrowing of an opening or passageway.

to the optic disk and gradual loss of vision, causing blindness in approximately 50% of affected individuals.

Additional conditions have sometimes occurred in conjunction with Rieger syndrome. Whether they are separate entities in which the Rieger eye malformations are present or part of Rieger syndrome is not determined. These conditions are:

- Myotonia (a condition in which the muscles do not relax after contracting).
- Myotonic dystrophy (a chronic progressive disease causing muscles to atrophy, slurred speech, failing vision, droopy eyelids, and general muscle weakness).
- Conductive deafness (hearing loss in which sound does not travel well to the inner ear).
- Less than average intellectual function associated with problems in learning and social behavior.

Diagnosis

This disorder can be detected soon after birth if the eye defects are visible. When the eye defects are not visible during the first month of life, Rieger syndrome is usually detected in early childhood when the eye and dental defects become apparent.

Molecular genetic testing for the *RIEG1* and *RIEG2* genes is not generally available. But since the molecular structure of the genes has been identified, the possibility now exists for DNA-based testing for diagnosis and genetic counseling.

Genetic counseling

Genetic counseling may be beneficial for patients and their families. Only one parent needs to be a carrier in order for the child to inherit the disease. A child has a 50% chance of having the disease if one parent is diagnosed with the disease and a 75% chance of having the disease if both parents have Rieger syndrome.

Prenatal testing

For couples known to be at risk for having a baby with Rieger syndrome, testing may be available to assist in prenatal diagnosis. Prior testing of family members is usually necessary for prenatal testing.

Either chorionic villus sampling (CVS) or amniocentesis may be performed for prenatal testing. CVS is a procedure to obtain a small sample of placental tissue, called chorionic villi tissue, for testing. Examination of fetal tissue can reveal information about the defects that leads to Rieger syndrome. Chorionic villus sampling can be performed at 10–12 weeks gestation.

Amniocentesis is a procedure that involves inserting a thin needle into the uterus and the amniotic sac and withdrawing a small amount of amniotic fluid. DNA can be extracted from the fetal cells contained in the amniotic fluid and tested. Amniocentesis is performed at 16–18 weeks gestation.

Tissue showing the gene mutation for Rieger syndrome type I or II obtained from CVS or in amniotic fluid is diagnostic.

Related disorders

A number of disorders are similar to Rieger syndrome. Comparisons may be useful for a differential diagnosis. These related disorders include:

- Cat-eye syndrome, a rare disorder marked by a cleft along the eyeball affecting the iris, the membrane that covers the white of the eyeball (choroid), and/or the retina and causing a vertical pupil; abnormalities such as small polyps or pits

QUESTIONS TO ASK YOUR DOCTOR

- How do the two types of Rieger syndrome differ from each other?
- Are prenatal tests for Rieger syndrome recommended? Why or why not?
- What are the most serious medical complications associated with Rieger syndrome?
- How should the medical progress of a child with Rieger syndrome be monitored throughout his or her life?

near the front of the outer ear; and absence of the opening, duct, or canal of the anus. Other symptoms may include mild intellectual disability and heart defects.

- Ectodermal dysplasias, a group of hereditary syndromes affecting the skin, its derivatives, and some other organs. Symptoms include predisposition to respiratory infection, eczema, poorly functioning sweat glands, abnormal hair and nails, and difficulties with the nasal passages and ear canals.
- Eye, anterior segment dysgenesis, a rare congenital disorder resulting in abnormal tissue development of the outer eye segment. In less severe cases, the back of the outer surface of the cornea is nontransparent (embryotoxin). Symptoms include ocular abnormalities and malformations of the teeth, abdominal wall, skeleton, and heart.

It is generally thought that Axenfeld anomaly, marked by defects limited to the outer part of the field of vision of the eye, should not be considered a separate entity of Rieger syndrome.

Treatment and management

A physician familiar with the range of problems seen in individuals with Rieger syndrome is important for appropriate health supervision. Treatment should include assistance finding support resources for the family and the individual with Rieger syndrome.

Treatment of Rieger syndrome is focused on treating the symptoms expressed. Depending on what they are, these treatments may include:

- Drug therapy for glaucoma; usually a topical beta blocker in the form of eye drops. Laser surgery may be performed on those patients in whom the pressure in the eye is not relieved by medications.
- Prostheses (false teeth) or other orthodontic interventions for dental malformations.

The single nucleotides (monomers) of RNA form a linear chain by linking their phosphate groups and sugars in phosphodiester bonds. RNA does not form a double stranded alpha-helix as does DNA. In some parts of the RNA molecule, there is folding into alpha-helical-like regions. Corresponding to their unique functions, mRNA, rRNA, and tRNA all have different three-dimensional structures. In higher eukaryotic organisms, different RNAs are found distributed throughout the cell—in the nucleus, cytoplasm, and also in cytoplasmic organelles such as mitochondria and, in plants, chloroplasts.

The nucleus is the chief site of RNA synthesis and the source of all cytoplasmic RNA, while mitochondria and chloroplasts synthesize their RNA from their own DNA. rRNA is synthesized by the nucleoli within the nucleus, while the high molecular weight precursor to cytoplasmic mRNA, sometimes termed heterogeneous nuclear or hnRNA, is transcribed on the DNA chromatin. Low molecular weight RNA also occurs in the nucleus and consists partly of tRNA and partly of RNA, which has a regulatory function in gene activation. The cytoplasm contains tRNA and rRNA in the ribosomes and mRNA in polysomes, or polyribosomes. The latter are the structural units of protein biosynthesis, consisting of several ribosomes attached to a strand of mRNA.

The function of mRNA is to transcribe the information held in DNA. In the cells of eukaryotic organisms, the first transcriptional product is the long, heterogeneous nuclear RNA, or hnRNA. This contains both the nucleotide sequences eventually transcribed into polypeptides and large tracts of sequences not translated. Nontranslated sequences are termed introns (or intervening sequences). Removal of introns, and other untranslated portions of the molecule, edits hnRNA into mRNA molecules. After editing removes as much as 90% of hnRNA, the resulting mRNA molecules are transported into the cytoplasm.

rRNA is located within ribosomes, the sites of protein biosynthesis. Ribosomes are large ellipsoid cytoplasmic organelles consisting of RNA and protein.

tRNA, the smallest known functional RNA, is essential for protein biosynthesis. Its purpose is to transfer a specific amino acid from the cytoplasm and incorporate it into the growing polypeptide chain on the polysome. Different tRNAs contain between 70 and 85 nucleotides. The most characteristic feature of tRNA is that it contains the anticodon, a sequence of three nucleotides specific for the mRNA codon sequence. There is at least one tRNA per cell bearing the anticodon for each of the 20 amino acids. The aminoacyl-tRNA (the tRNA carrying the amino acid) binds to the large subunit of a ribosome, where antiparallel base pairing occurs between the anticodon of the tRNA and the complementary codon of the associated mRNA. The specificity of this base pairing

ensures that the amino acid inserts into the correct position in the growing protein polypeptide chain. During translation, the deacylated tRNA (i.e., with its amino acid removed) is released from the ribosome and becomes available once again for recharging with its amino acid.

DNA-dependent RNA synthesis is the process of RNA synthesis on a template of DNA. According to the rules of base pairing, the base sequence of DNA determines the synthesis of a complementary base sequence in RNA. Assisted (catalyzed) by the enzyme RNA polymerase, the growing RNA chain releases from the template so that the process can start again, even before the previous molecule is complete. Termination codons and a termination factor known as rho-factor end the synthesis process. In certain viruses, RNA-dependent RNA synthesis occurs, with the viral RNA acting as a template for the synthesis of new RNA.

Roberts SC phocomelia

Definition

Roberts SC phocomelia is a rare genetic condition that causes severe abnormalities in arm and leg bones. Other abnormalities, such as intellectual disability, may also be present.

Description

Roberts SC phocomelia was first described in the year 1919. In the past, Roberts SC phocomelia syndrome

was described as two separate syndromes: Roberts syndrome and SC or pseudo-thalidomide syndrome. More recent examination, however, indicated that they are the same disorder. The term “pseudo-thalidomide” was originally used to describe individuals with limb shortening, as the medication thalidomide is known to cause limb abnormalities in the babies of women taking it during pregnancy.

Phocomelia is a condition in which the hands and feet are present, but the arms and legs are absent. The hands and feet are attached directly to the body. Usually there is greater shortening in the arms than in the legs. People with Roberts SC phocomelia syndrome have varying degrees of hypomelia, which means that the limbs are not fully developed. Some are born without the upper bones of the arms or the legs. This is referred to as tetraphocomelia. Some people, though, have a less severe form of limb shortening.

In addition to the limb abnormalities, 80% of individuals with the syndrome have a small head (microcephaly). In addition, most people with the syndrome have some degree of intellectual disability. Most also have facial problems affecting the development of the upper lip (cleft lip), and incomplete development of the palate (the roof of the mouth).

Genetic profile

Roberts SC phocomelia is inherited in an autosomal recessive fashion. This is a pattern in which the child receives one nonfunctioning (abnormal) gene from each parent. When a woman and a man who both carry one abnormal gene for Roberts SC phocomelia have children, there is a 75% chance that they will each pass along the gene for the syndrome and a 25% chance that they will have a child with the fully expressed syndrome. People who are termed “carriers” are not affected by the disorder, as they have only one copy of the gene that causes Roberts SC phocomelia. The chances are 50% that they will have a child who is also a carrier of the disorder. The chances are 25% that they will have a baby who is neither a carrier nor affected with Roberts SC phocomelia.

The specific gene that causes the syndrome is not yet known, and there is no direct genetic test to identify a potential carrier of the disease.

In many of the individuals who have been diagnosed with Roberts SC phocomelia, a unique feature may be observed on some of their chromosomes. The exact association of this unusual observation with the syndrome is not yet understood.

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman’s abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Amniotic fluid—The fluid that surrounds a developing baby during pregnancy.

Cell—The smallest living units of the body, which group together to form tissues and help the body perform specific functions.

Genetic test—Testing of chromosomes and genes from an individual or unborn baby for a genetic condition. Genetic testing can only be done if the gene is known.

Ultrasound evaluation—A procedure that examines the tissue and bone structures of an individual or a developing baby.

Demographics

While the exact number of people with the syndrome is not known, as some infants who die before or shortly after birth are never diagnosed or are diagnosed incorrectly, there have been around 150 confirmed reports of the condition. The syndrome affects males and females equally. There is no specific country or region of the world where the disorder is more common.

Signs and symptoms

In the bones of the lower arm (radius and ulna), limb shortening or absence of limbs is evident in approximately 97% of people with the syndrome. The upper arm (humerus) is affected 77% of the time. A missing or shortened thigh bone (femur) occurs in about 65% of affected individuals. The bones in the lower leg (tibia and fibula) are shortened or absent in 77% of those with the disorder.

It is often very hard to flex or bend the knees, ankles, wrists, and/or elbows. While the feet and hands are almost always present, there may be fewer than normal fingers and toes, or shortened fingers. Sometimes the fingers are fused together (syndactyly).

People with the syndrome are smaller than other babies the same age, both before and after birth. Babies

with Roberts SC phocomelia syndrome may have thin hair that is often described as silvery in color. In addition, most people with Roberts SC phocomelia syndrome are born with a cleft lip (a failure of the upper lip to close completely) and cleft palate (an opening in the roof of the mouth). Other abnormalities that may occur include a small and underdeveloped chin, a short neck, heart and kidney problems, prominent and widely spaced eyes, and unusually shaped ears.

Diagnosis

This disorder has been diagnosed during pregnancy at 12 weeks, through a test called an ultrasound evaluation. In these incidences, developmental problems with the growth and formation of both the arms and legs were noted. Sometimes the syndrome cannot be diagnosed by ultrasound until later in the pregnancy, when the limb shortening or absence becomes more obvious, and sometimes it cannot be diagnosed by ultrasound at all. Other abnormalities that might be seen by ultrasound include cleft lip, increased distance between the eye sockets, and extra fluid in some of the structures of the brain (hydrocephalus). Excess amniotic fluid levels, kidney problems, and an opening in the spine (spina bifida) have also been found. However, an exact diagnosis of the syndrome cannot be made by ultrasound evaluation alone.

Checking for the unusual chromosome feature is done through amniocentesis, a procedure that collects the developing fetus's cells for evaluation. But this test is not typically recommended, because not all affected individuals have this chromosome finding. In addition, the chromosome is not always evident in the cells from the amniotic fluid.

There is no accurate prenatal test to diagnose the syndrome during pregnancy.

After a baby is born with characteristics of Roberts SC phocomelia syndrome, a diagnosis can be made through a complete physical examination. In addition, analysis of the baby's chromosomes may also be useful. The chromosomes can be analyzed through a blood or tissue sample.

Treatment and management

At this time there is no treatment available for individuals with Roberts SC phocomelia syndrome. The shortness or absence of limbs makes it difficult for any type of limb-lengthening therapies to be useful in most instances.

Prognosis

The majority of severely affected individuals will die in the womb, or during or shortly after birth. Those who

QUESTIONS TO ASK YOUR DOCTOR

- What are the usual signs and symptoms associated with Roberts SC phocomelia syndrome?
- Please explain the meaning of the term "phocomelia."
- Are there prenatal tests of Roberts SC phocomelia syndrome, and under what circumstances would they be recommended?
- What is the progress for a child diagnosed with Roberts SC phocomelia syndrome?

survive will have very obvious growth deficiency as well as intellectual disability. Babies who are not as severely affected, with less dramatic limb shortening and no facial cleft, have a better overall prognosis.

Robinow syndrome

Definition

Robinow syndrome encompasses two different hereditary disorders, both rare, with a similar pattern of physical abnormalities. Typical features of these conditions include mild-to-moderate short stature, distinctive facial features, skeletal abnormalities, and abnormal development of the genitalia.

Description

A family that included several individuals with a characteristic pattern of facial features, accompanied by short stature (dwarfism), skeletal abnormalities, and underdevelopment (hypoplasia) of the external genitalia (sex organs) was first described in 1969 by Dr. Meinhard

Robinow. He named the condition “fetal face syndrome,” because the facial features are similar to those of a normal fetus. Only later was Dr. Robinow’s name used to identify the syndrome. Other names for the condition include Robinow dwarfism, as well as “acral dysostosis with facial and genital abnormalities.”

Skeletal abnormalities of varying types and severity occur in every case of Robinow syndrome. Most people with the condition have abnormal development of specific bones of the arms and legs resulting in some degree of short stature. Spinal abnormalities are also common. Most females are fertile, but only a few males with the condition have had children.

Genetic profile

Chromosomes are the microscopic structures inside cells that carry the genes. Each cell of the body contains 46 chromosomes in 23 pairs. The exceptions are sperm and eggs, which normally carry 23 chromosomes—one of each pair. The first 22 pairs of chromosomes in humans are known as the autosomes. An inherited condition is autosomal if the abnormal gene that causes it resides on one of the first 22 pairs of chromosomes.

Several years after Dr. Robinow’s first report, it became clear that some families affected by Robinow syndrome have an autosomal dominant pattern of inheritance, while in other families the syndrome is inherited

Robinow syndrome: pedigree analysis chart (Gale)

as an autosomal recessive trait. The reason for this genetic discrepancy is unknown.

Dominant inheritance means that an error in only one gene of a pair is enough to produce symptoms of the disorder. In other words, the abnormally functioning gene of the pair is dominant over the normal gene. A person who carries the gene for autosomal dominant Robinow syndrome has a 50% chance of passing it on to each of his or her offspring.

In autosomal recessive inheritance, a person must have errors in both copies of a gene pair in order to be affected. Someone who carries just one copy of the disease gene has another normally functioning gene of that pair to compensate for it. Therefore, a carrier of a single recessive gene typically shows no symptoms of the disorder. If two people who both carry the gene for recessive Robinow syndrome conceive a pregnancy, there is a 25% chance that they will each contribute the Robinow syndrome gene and have an affected child.

Mutations in the *ROR2* gene are responsible for recessive Robinow syndrome. The exact function of the protein encoded by the *ROR2* gene has not been determined, and the gene responsible for dominant Robinow syndrome has not been located.

Demographics

Both the dominant and recessive forms of Robinow syndrome are rare. There are fewer than 200 people affected worldwide. Dominant Robinow syndrome does not appear to occur more frequently in any particular ethnic group. A significant proportion of recessive Robinow syndrome cases, however, have occurred in Czechoslovakia, Turkey, and the Middle East. In addition, some children with recessive Robinow syndrome have parents who are genetically related (consanguineous), such as first cousins. Parental consanguinity is sometimes seen in rare, autosomal recessive conditions, since people who are genetically related are more likely to carry the same recessive gene(s).

Signs and symptoms

The signs and symptoms of Robinow syndrome can be grouped into those that involve the face, those that affect the skeleton, and those affecting the genitalia. There is a good deal of overlap of symptoms between the dominant and recessive forms. In general, however, people with recessive Robinow syndrome tend to be more severely affected.

The facial features of Robinow syndrome include a flat nasal bridge, slightly upturned nose, triangular-shaped mouth, protruding forehead (frontal bossing),

KEY TERMS

Acromelic—The anatomical term used to denote the end of a limb (arm or leg). In the context of Robinow syndrome, it refers to bones of the hands and feet.

Brachymelia—A general medical term used to describe short limbs.

Hypertelorism—A wider-than-normal space between the eyes.

Hypoplasia—Incomplete or underdevelopment of a tissue or organ.

Mesomelic—The anatomical term used to describe the middle of a limb. The bones that constitute the middle of the arm are the radius and ulna, and mesomelic bones of the leg are the tibia and fibula.

Vertebra—One of the 23 bones that compose the spine. "Vertebrae" is the plural form.

wide space between the eyes (hypertelorism), wide eye openings, low-set ears, long philtrum (groove from nose to upper lip), small lower jaw (micrognathia), excessive growth of the gums, and crowding of teeth.

People with Robinow syndrome have what is known as acromesomelic brachymelia. Acromesomelic refers to bones at the end (acro) and in the middle (meso) of the limbs. Brachymelia is the medical term for short limbs. Thus, short limbs in Robinow syndrome are due to shortened bones in the hands, feet, lower arms, and lower legs. Dominant Robinow syndrome is associated with normal height to borderline short stature, while recessive Robinow syndrome always results in short stature. Abnormalities of the spine often involve misshapen or fused vertebrae (so-called segmentation defects), as well as scoliosis. Vertebral abnormalities are more frequent and more pronounced in the recessive form of Robinow syndrome. Ribs may be fused together or abnormally shaped, and this may lead to pectus excavatum (sunken breastbone).

Males with Robinow syndrome typically have a hypoplastic penis, and may have undescended testicles (cryptorchidism). Females can have a small clitoris and hypoplastic labia. A dysfunctional sex-steroid response-and-feedback mechanism may be partly to blame for some of the signs of Robinow syndrome, particularly the genital anomalies.

Physical anomalies found less frequently in Robinow syndrome include heart defects, kidney abnormalities, cleft lip/palate, and hearing loss. Most individuals with

QUESTIONS TO ASK YOUR DOCTOR

- What is the genetic mechanism responsible for Robinow syndrome?
- What are the most distinctive physical characteristics of a child with Robinow syndrome?
- Are there prenatal tests I can have to discover if my child is likely to have Robinow syndrome?
- Where can I obtain additional information about Robinow syndrome on the Internet?

Robinow syndrome have normal intelligence, but a few have mild intellectual disability.

Diagnosis

The diagnosis of Robinow syndrome is made by physical examination. Several other genetic syndromes have some of the same physical signs as Robinow syndrome, which can make arriving at the correct diagnosis more difficult. However, the pattern of skeletal abnormalities in Robinow syndrome has a distinct appearance when seen on x-rays, which may help in confirming the diagnosis. Testing of the *ROR2* gene is theoretically possible for recessive Robinow syndrome, but would only be offered on a research basis, if at all.

Treatment and management

There is no cure for either type of Robinow syndrome. Future research may help to determine if some type of hormone therapy can be used to treat the short stature and/or hypoplastic genitalia. Otherwise, no specific protocol is recommended for managing children and adults with either form of the condition. An orthopedic surgeon might be needed to address any problems that arise related to skeletal abnormalities, especially in the spine. Special educational intervention would be indicated for anyone with learning disabilities or intellectual disability.

People with pronounced physical signs of the condition (short stature and facial features) may have difficulties with their self-image. Males with a hypoplastic penis can present a special problem. In those cases, added psychological and social support is particularly important. Genetic counseling should be offered to individuals/families affected by Robinow syndrome to help them understand the condition, its inheritance, and any testing (including prenatal) that might be available.

Prognosis

Any one person with Robinow syndrome may have a good prognosis, depending on how well they cope with their particular symptoms. A child with recessive Robinow syndrome is more likely to have long-term difficulties than a child with the dominant form of the condition, but no blanket statements can be made. Overall, lifespan should not be significantly decreased in most cases of Robinow syndrome, since the majority of affected individuals do not have life-threatening complications.

Rothmund-Thomson syndrome

Definition

Rothmund-Thomson syndrome (RTS) is an extremely rare inherited disorder that appears in infancy and features skin degeneration (atrophic dermatosis), clouding of the lenses of the eyes (juvenile cataracts), skeletal abnormalities, short stature, and an increased risk of skin and bone cancers.

Description

Rothmund-Thomson syndrome is usually first apparent between three and six months of age. This disorder is characterized by early sun sensitivity and progressive degeneration or wasting (atrophy) of the skin, as well as scarring and abnormal pigmentation of the skin. Other characteristic signs include sparse hair; clouding of the lenses of the eyes (juvenile cataracts); short stature; malformations of the face and head, teeth, nails, and bone; and other physical abnormalities. In rare cases, intellectual disability may be present.

The syndrome was first described in 1868 by August von Rothmund, a German ophthalmologist, and in both 1923 and 1936 by Matthew S. Thomson, a British dermatologist. Both independently noted a familial disorder with cataracts, saddle nose, and skin degeneration. It is believed that Thomson's finding was the same disease that was seen long before by Rothmund. Other names for Rothmund-Thomson syndrome include poikiloderma congenita and poikiloderma atrophicans with cataract.

Genetic profile

Rothmund-Thomson is attributed to a mutation in a gene located on chromosome 8. Mutations in the gene *RecQL4* (chromosomal locus 8q24), also called the Rothmund-Thomson gene, have been identified in four patients with Rothmund-Thomson syndrome.

Rothmund-Thomson syndrome is inherited as an autosomal recessive trait. This means that both parents have one copy of the Rothmund-Thomson gene but do not have the disease. Each of their children has a 25% chance of not having the gene, a 50% chance of having one Rothmund-Thomson gene (and, like the parents, being unaffected), and a 25% risk of having both Rothmund-Thomson genes and the disease.

Demographics

There is no specific population group that is at greater risk for this disorder, although it is more common in women (2:1). Evidence of Rothmund-Thomson syndrome has been found to occur in all races and many nationalities. The majority of affected people are from full-term pregnancies. As of 2015, 300 cases had been reported worldwide. The number of carriers for Rothmund-Thomson syndrome is unknown.

Signs and symptoms

The major characteristics of Rothmund-Thomson syndrome are skin abnormalities, short stature, juvenile cataracts, small hands, and delayed activities of the

KEY TERMS

Alopecia—Loss of hair or baldness.

Atrophic dermatosis—Wasting away of the skin.

Depigmentation—Loss of pigment or skin color.

Dysplastic—The abnormal growth or development of a tissue or organ.

Edema—Extreme amount of watery fluid that causes swelling of the affected tissue.

Frontal bossing—A term used to describe a rounded forehead with a receded hairline.

Hyperpigmentation—An abnormal condition characterized by an excess of melanin in localized areas of the skin, which produces areas that are much darker than the surrounding unaffected skin.

Hypogonadism—Small testes in men and scarce or irregular menstruation for females.

Keratosis—A raised thickening of the outer horny layer of the skin.

Microdontia—Small teeth.

Poikiloderma—A condition characterized by skin atrophy, widening of the small blood vessels (telangiectasia), and pigment changes giving a mottled appearance.

Prognathism—A protruding lower jaw.

Saddlenose—A sunken nasal bridge.

Telangiectasia—An abnormal widening of groups of small blood vessels in the skin.

ovaries in females or testes in males. Symptoms vary from individual to individual.

Skin abnormalities usually appear in infancy, between three and six months of age. Skin changes begin as red inflamed patches, occasionally with blistering, on the cheeks along with swelling and then spread to other areas of the face, the arms and legs, and buttocks. Skin inflammation eventually subsides and a condition develops known as poikiloderma, characterized by abnormal widening (dilation) of groups of small blood vessels (telangiectasia), skin tissue degradation (atrophy), and patchy areas of abnormally decreased and/or unusually increased brown pigmentation (depigmentation and hyperpigmentation), giving the skin a mottled look. Skin that is exposed to the sun usually shows greater abnormalities. Sun sensitivity typically continues throughout the affected person's life. Those with extreme sun sensitivity can develop thickening of the skin (keratosis) of the face, hands, and feet, or cancerous skin changes later

in life. Affected individuals are at increased risk of developing skin cancers (basal cell carcinoma and squamous cell carcinoma) and bone cancer (osteosarcoma).

There are many other physical abnormalities that affect people with Rothmund-Thomson syndrome. Juvenile cataracts, the clouding of the lenses of the eyes, develop in almost half of the people with RTS between the ages of four and seven. Severe growth delays result in short stature throughout life. Skeletal abnormalities such as unusually small hands and feet are common. Less typical are stubby fingers and toes, underdeveloped (hypoplastic) or absent thumbs, and/or underdeveloped (hypoplastic) or missing forearm bones (ulna and radii). Hypogonadism, the deficient activity of the ovaries in females or testes in males, causes irregular menstruation in females, and delayed sexual development and reduced fertility in both males and females. Facial skeletal abnormalities include a triangular-shaped face with a prominent forehead (frontal bossing), a sunken nasal bridge (saddle nose), and a protruding lower jaw (prognathism). Scalp hair is usually thin and fine, although alopecia (balding) occasionally occurs in early childhood. Often the eyebrows and eyelashes are sparse or absent. Dental abnormalities include excessive cavities, unusually small teeth (microdontia), or delayed or failure of teeth to erupt. Dysplastic, or abnormally developed, nails are also seen in many people with Rothmund-Thomson syndrome.

Diagnosis

A diagnosis of Rothmund-Thomson syndrome is made based on clinical examination. Mutations of the *RecQL4* gene have been found two-thirds of individuals with Rothmund-Thomson syndrome.

There are no published diagnostic criteria. Diagnosis is usually based on the presence of the characteristic poikilodermatous rash in childhood, along with one or more of the following features: small stature, sparse or absent hair, cataracts, and cancer.

Treatment and management

Essential management of Rothmund-Thomson syndrome includes avoiding sun exposure and diligently using sunscreen that has both UVA and UVB protection.

An ophthalmologic evaluation for the detection and management of cataracts is recommended for affected people on an annual basis up to age 15. Surgical removal of significant cataracts may be necessary.

Because skin cancer is a risk, it is important to monitor the affected individual closely for lesions with unusual color or texture. They should also be watched

QUESTIONS TO ASK YOUR DOCTOR

- At what age can Rothmund-Thomson syndrome be diagnosed, and how is that diagnosis made?
- How common is Rothmund-Thomson syndrome, and are there certain populations at greater risk for the disease than the general public?
- What types of treatment are recommended for Rothmund-Thomson syndrome, and what risks are associated with each kind of treatment?
- What is the prognosis for an infant diagnosed with Rothmund-Thomson syndrome?

carefully for any signs and symptoms of osteosarcoma, a cancerous bone tumor, including bone pain, swelling, or a growing lesion on the arms or legs.

Pulsed-dye laser therapy has been used to treat the widening of small blood vessels (telangiectasia). Medications called retinoids can reduce the potential for skin cancer. Keratolytic drugs are used to cause thick skin to swell, soften, and then fall away.

Prognosis

Individuals with Rothmund-Thomson syndrome usually have a normal lifespan, although an increased risk for bone and skin cancer has been found. Most affected individuals will have normal intelligence; however, learning disabilities and intellectual disability have been reported in a small number of patients.

Rubinstein-Taybi syndrome

Definition

Rubinstein-Taybi syndrome (RSTS) is a rare genetic disorder involving moderate to severe intellectual impairment, short stature, broad thumbs and great toes, and characteristic facial features. First described in 1963 by the American physicians Dr. Jack Rubinstein and Dr. Hooshang Taybi, over 550 cases have since been reported.

Description

The clinical picture of RSTS is highly variable. The most prominent features include intellectual impairment, thumb and great toe abnormalities, and distinct facial characteristics.

RSTS may also be referred to as broad-thumb-hallux syndrome or Rubinstein syndrome. The abbreviation for Rubinstein-Taybi syndrome is denoted “RSTS” or “RTS,” although “RSTS” is preferred so as not to be confused with other syndromes such as Rett syndrome and Rothmund-Thomson syndrome.

Genetic profile

RSTS may be inherited if both parents carry a mutation of one of the genes known to cause RSTS; however, the majority of people with RSTS have random, or *de novo*, genetic mutations that caused their RSTS.

KEY TERMS

Great toe—The first and largest toe on the foot.

Hallux—The great toe.

Recurrence risk—The possibility that the same event will occur again.

Respiratory—Having to do with breathing.

Of the cases of inherited RSTS, more than 55%, are caused by mutations in the *CREBBP* gene. Located on chromosome 16, the *CREBBP* gene carries instructions for making the CREB binding protein, a protein that is important to the activity of many other genes and is important in cell growth and division. The functions of the CREB protein are essential for normal fetal development. Researchers have not identified the exact mechanisms; however, mutation in only one of the pair of *CREBBP* genes cause only half the normal amount of CREB protein to be produced. This reduction interrupts normal development both before and after birth, causing the symptoms of RSTS.

Another inherited genetic cause of RSTS is mutation of the *EP300* gene. This gene is important in the formation of a protein called p300. Like the CREB protein, p300 is significant in cell growth and division and in fetal development. Similarly, mutations in the *EP300* gene cause too little of the p300 protein to be made and this leads to the symptoms of RSTS. Researchers estimate that approximately 33% of inherited RSTS cases are caused by mutations in the *EP300* gene.

RSTS caused by mutations of the *CREBBP* and *EP300* genes are inherited in an autosomal dominant pattern, which means that only one copy of the mutated gene must be present for a person to have RSTS.

Most cases of RSTS, however, are sporadic. That is, the majority of affected individuals do not have a parent with RSTS; rather, RSTS arose due to a new mutation in the *CEBBP* gene. Sporadic mutations in genes occur by chance. They are rare and there is nothing a person can do during a pregnancy to cause or prevent them.

Demographics

The incidence of RSTS has been estimated at between 1 in 100,000 and 1 in 125,000 live births. Males and females are affected equally. Cases of RSTS have been observed throughout the world. Although RSTS is thought to be a rare disease, more cases are being diagnosed each year. In part, this is thought to be due to

physicians' increasing awareness of the signs and symptoms involved in RSTS.

Signs and symptoms

RSTS is a genetic disorder involving primarily physical malformations and intellectual impairment.

Babies with RSTS may be born small compared to other newborns. They often have trouble feeding and may need to be assisted in this area. In conjunction with feeding problems, there may be respiratory (breathing) difficulties.

As the child matures, growth remains delayed, with short stature persistent throughout life. An average height of 60 in (153 cm) in males and 58 in (147 cm) in females and an average weight of 106 lb (48 kg) in males and 120 lb (55 kg) in females has been reported.

Developmental milestones are usually delayed. Although most children with RSTS learn to walk and talk, they tend to develop these skills much later than their peers. For example, the average age at which children with RSTS learn to walk is 30 months, compared to 12 months in unaffected children.

There are several unique physical characteristics associated with RSTS. Typical facial features include down-slanting eyes, beaked nose, and the fleshy septum of the nose extending beyond the nostrils. By two to three years of age, most affected children grow into what is considered the classic physical picture of RSTS. Because of their similar facial appearances, they may resemble other children with RSTS as much as or more than they resemble family members.

The most well-known features of patients with RSTS are the broad thumbs and great toes (halluces). This finding may be observed at birth, although some patients with RSTS have only broad thumbs, only broad toes, or neither.

Other findings that occur on a less frequent basis include malignant (cancerous) and benign (noncancerous) tumors, chronic ear infections, early onset of breast development in females, kidney abnormalities, high arched palate (roof of the mouth), malformed teeth (named talon cusps after their shape), heart defects, small head, and short upper lip with a pouting bottom lip.

Intellectual impairment of varying degrees is a constant in RSTS. Affected individuals may present mild to severe intellectual impairment. They have particular difficulty in expression through speech. Although affected individuals are usually able to understand what is spoken to them, they have a difficult time responding with spoken words. In general, it has been observed that many

QUESTIONS TO ASK YOUR DOCTOR

- How is Rubinstein-Taybi syndrome distinguished from other genetic disorders with similar signs and symptoms?
- Are there organizations from which I can get additional information about this genetic disorder?
- If I have one child with Rubinstein-Taybi syndrome, what is the probability of having a second child with the same condition?
- What kinds of medical care will I have to provide for my Rubinstein-Taybi child as he or she grows older?

patients with RSTS do not progress beyond a first-grade level.

It has been noted that affected individuals tend to have happy, outgoing, and energetic personalities. They have been described as people who “know no strangers.” People with RSTS tend to smile often, although, due to their physical differences, this smile is sometimes described as a grimace.

Not every person with RSTS will have all of the aforementioned medical, physical, and social characteristics. Although people with RSTS have much in common, it is important to remember that each person is unique with his or her own qualities and challenges.

Diagnosis

Diagnosis is usually based on clinical findings; therefore, the doctor will perform a complete physical examination and record a detailed medical history. Laboratory techniques for definitive diagnosis by genetic screening may be used if mutations in the *CEBBP* gene or *EP300* gene are suspected; however, these tests are only able to identify approximately 25% of affected individuals. This is due to the considerable number of different changes within the same gene that all may lead to RSTS.

Prenatal diagnosis is available for RSTS; however, again, only approximately 25% of cases are picked up by current available techniques. Because the physical features associated with RSTS are difficult to distinguish prenatally, and the available DNA test does not identify most cases, the vast majority of individuals with RSTS are diagnosed after birth.

The age at which a person is diagnosed varies from patient to patient due to the range in severity of clinical findings. Those with a more mild presentation tend to be diagnosed later in life. Diagnosis may be more difficult in non-Caucasian persons due to the great majority of research and published data having been done on Caucasian patients.

Misdiagnosis is sometimes made between RSTS and Saethre-Chotzen syndrome because of their similar clinical findings.

A correct diagnosis is important when providing a family with genetic counseling. A family with a child with RSTS can have many questions. Genetic counseling may be helpful in providing the family with some answers, including information about the risk of having another child with RSTS.

In general, a recurrence risk of 0.1% is given to couples that have had one child with RSTS. For individuals with RSTS there is a 50% chance of passing the condition on in each pregnancy.

Treatment and management

Treatment and management is aimed at encouraging and supporting cognitive development and alleviating medical symptoms. There is no cure for Rubinstein-Taybi syndrome.

Medical problems, such as ear and respiratory infections, are treated as they occur. Chronic ear infections may lead to hearing loss and it is therefore important to have this infection treated as quickly as possible.

Early intervention and occupational and physical therapy are encouraged along with behavioral management. It has been shown that children with intellectual impairment and developmental delay, due to any cause, benefit from these therapies. In particular, for children with RSTS, speech therapy and alternate forms of communication, such as sign language, have been found to be helpful. Alternative avenues of communication may help children with RSTS express their thoughts and feelings and reduce the frustration they may feel at not being understood verbally.

Prognosis

Prognosis is variable due to the wide range of presentations among affected individuals. Intellectual impairment and developmental delay may range from mild to severe, with a reported average IQ of 51 (the general population average IQ is 100). Medical problems also vary in number and severity.

Most individuals with RSTS will have a normal lifespan. As adults, affected individuals may live in group

homes or supervised apartments. Many work in sheltered workshops or in supervised employment situations.

Individuals with RSTS are capable of having children of their own. In a study of 502 individuals with RSTS, two had reproduced. In total they had three children, one affected with RSTS and two unaffected. It has also been the case that a very mildly affected woman was not diagnosed with RSTS until her child was born with the same disorder.

Russell-Silver syndrome

Definition

Russell-Silver syndrome (RSS) is one of the recognized forms of intrauterine growth retardation (IUGR) disease. It was first independently described by H. K. Silver in 1953 and by A. Russell in 1954.

Description

Russell-Silver syndrome is one of more than 300 recognized forms of genetic disorders that lead to short stature. It is characterized by:

- the presence of a triangular-shaped face
- an incurving fifth finger (clinodactyly)
- low birth weight and length (intrauterine growth retardation, or IUGR)
- a poor appetite in the first few years of life

This disorder is alternately known as Russell syndrome, Silver syndrome, or Silver-Russell syndrome. Some clinicians use the term “Russell syndrome” to indicate this disorder when the size of the sides of the body and the limbs are equal, and the term “Silver syndrome” to indicate this disorder when the size of the sides of the body or the length of the limbs is different (body asymmetry).

Genetic profile

The exact genetic cause, or causes, of RSS have not been fully identified. It is currently believed that almost all cases of RSS are the result of mutations on a gene, or possibly more than one gene, on chromosome 7.

Demographics

RSS has an estimated incidence rate of 1 in 75,000 to 100,000 people. Almost all cases of RSS are sporadic; that is, they appear for the first time in individuals with no family history of RSS. However, case studies indicating all three modes of inheritance—autosomal recessive, autosomal dominant, and X-linked—have been reported.

RSS does not appear to affect any particular race or ethnic group in a greater frequency than others. It is also observed equally in males and females.

Signs and symptoms

There are six characteristics that define Russell-Silver syndrome: a triangular-shaped face; down-turned corners of the mouth; inwardly curved little fingers (clinodactyly); a combination of low birth weight (intrauterine growth retardation) and short birth length after a full-term gestation; a long, narrow head (scaphocephaly); and a poor appetite that causes slow growth after birth. These characteristics are commonly observed in people affected with RSS.

Several other characteristics are found in most, but not all, RSS-affected individuals. These include:

- low blood sugar (hypoglycemia) in infancy and early childhood

KEY TERMS

Body asymmetry—Abnormal development of the body in which the trunk and/or the limbs are not of equal size from one side of the body to the other.

Clinodactyly—An abnormal inward curving of the fingers or toes.

Delayed bone age—An abnormal condition in which the apparent age of the bones, as seen in x-rays, is less than the chronological age of the patient.

Hypoglycemia—An abnormally low glucose (blood sugar) concentration in the blood.

Intrauterine growth retardation—A form of growth retardation occurring in the womb that is not caused by premature birth or a shortened gestation time. Individuals affected with this condition are of lower than normal birth weight and lower than normal length after a complete gestation period.

Precocious puberty—An abnormal condition in which a person undergoes puberty at a very young age. This condition causes the growth spurt associated with puberty to occur before the systems of the body are ready, which causes these individuals to not attain normal adult heights.

Russell syndrome—An alternative term for Russell-Silver syndrome. Many doctors use this term to mean a Russell-Silver syndrome affected individual who does not have body asymmetry.

Scaphocephaly—An abnormally long and narrow skull.

Silver syndrome—An alternative term for Russell-Silver syndrome. Many doctors use this term to mean an individual with Russell-Silver syndrome who also has body asymmetry.

- unequal body and limb size from one side of the body to the other (body asymmetry)
- late closure of the soft spot in the front of the skull
- a broad forehead
- a small chin and jaw
- crowding of the teeth or abnormally small teeth caused by a smaller than normal jaw
- an abnormally thin upper lip
- low-set, small, and prominent ears
- fusion or webbing of the toes (syndactyly)
- poor muscle tone (hypotonia)

- a condition in which the bones are not as mature as the bones of a typical person of the same age (delayed bone age)
- developmental delays

In males affected with RSS, undescended testicles and a misplacement of the urethral opening (hypospadias) on the bottom of the penis rather than on the tip of the glans is often seen.

People affected with RSS may show other symptoms on a less uniform basis. These include:

- water on the brain
- a bluish coloration of the whites of the eyes
- a highly arched palate
- an absence of certain teeth
- frequent ear infections caused by fluid in the ear, which can lead to temporary hearing loss
- migraine headaches
- a curvature of the spine (scoliosis) or other problems with the spine, often caused by body asymmetry
- abnormalities of the kidneys
- an abnormally early onset of puberty (precocious puberty)
- irregularly colored spots on the skin (café-au-lait spots)
- high energy levels
- attention-deficit disorder (ADD)
- fainting spells

Diagnosis

Diagnosis of RSS is generally accomplished by performing a genetic test on cells grown from a skin sample. This test must be performed prior to the fifth year of life and it is not always accurate.

A diagnosis of RSS is supported by examination of the affected individual's growth curve and daily food intakes. In a child affected with RSS, these will fall well short of the mean for children of the same age.

Body measurements for asymmetry and x-rays to determine the bone age versus the actual age of the patient are also useful. Additionally, a blood test indicating hypoglycemia may indicate RSS. When RSS is suspected in males, an examination of the genitals may reveal undescended testicles or a misplacement of the urethral opening.

Treatment and management

Treatment of RSS varies on a case-by-case basis depending on the symptoms of the affected individual.

QUESTIONS TO ASK YOUR DOCTOR

- Please explain the meaning of the expression "intrauterine growth retardation."
- How I am responsible for my child's having Russell-Silver syndrome?
- What kinds of treatment will my child need because of his genetic disorder?
- What is your prognosis for the child's long-term development?

Dietary changes to increase food intake are required by all people with RSS. Many patients with RSS also require a diet high in sugars to treat hypoglycemia. When the necessary food intake cannot be accomplished by dietary changes, it may be necessary to treat patients with the antihistamine periactin, which also serves as an appetite stimulant. Some patients may also benefit from a feeding pump or gastrostomy. Gastrostomy is a surgical procedure in which a permanent opening is made directly in the stomach for the introduction of food.

In cases of severe growth retardation, certain people will require the administration of an artificial form of growth hormone (recombinant growth hormone) to stimulate growth, increase the rate of growth, and to increase their final adult height.

Ear tubes may be required to improve fluid drainage from the ears of some patients affected with RSS.

In cases of body asymmetry, limb-lengthening surgeries may be recommended. Alternatively, shoe lifts may be all that is necessary for the attainment of a normal gait.

Depending on the severity of physical, emotional, and psychological symptoms, some affected individuals may benefit from physical and/or occupational therapy. If ADD or other developmental problems exist, individuals with RSS may require educational assistance, such as remedial reading. In cases where the jaw is extremely small, talking may be difficult. These patients may require speech therapy.

Precocious puberty is the entrance of a child into puberty prior to the age of eight or nine. This early onset of puberty is generally accompanied by a growth spurt prior to puberty. While entering puberty before one is emotionally ready is certainly a serious problem, it is the growth spurt prior to puberty that is of major medical significance and concern.

If this growth spurt occurs prior to puberty, it is generally not as robust as if it had occurred during puberty, which causes the individual undergoing this growth spurt to grow less than a person who undergoes this process during puberty. The result is that a person who undergoes precocious puberty will generally end up much shorter in adulthood than his or her peers.

There are three hormonal therapies available in the United States to treat precocious puberty. Histrelin (trade name: Supprelin) is administered by daily injection. Leuprolide acetate (trade name: Lupron) is available as a depot formulation every four weeks. A depot formulation places medication in a tiny pump that is attached to the patient's body and releases the medication over time. Nafarelin acetate (trade name: Synarel) is administered as a nasal spray three times daily. Because of the age of people being treated, Lupron is most often the medication of choice because it is only administered once a month.

Some doctors have noticed that persons affected with RSS may have a slightly elevated chance of developing Wilms' tumor, the most common form of kidney cancer. Most cases of this type of cancer occur before the age of eight, and this condition is extremely rare in adults. It is important that children with RSS be screened with ultrasound every three months until the age of eight to make sure they have not developed Wilms' tumor. Wilms' tumor is quite treatable via surgery, chemotherapy, and/or radiation.

Prognosis

With proper medical treatment to address their individual symptoms, people affected with RSS do not, in general, have a reduced quality of life relative to the remainder of the population. As these people age, the symptoms of RSS tend to become less noticeable: the triangular shape of the face tends to lessen, muscle tone

and coordination improve, appetite improves, speech improves, and learning occurs. An affected adult is generally not less happy and/or healthy than any other person.

Saethre-Chotzen syndrome

Definition

Saethre-Chotzen syndrome is an inherited disorder that affects 1 in every 50,000 individuals. The syndrome is characterized by early and uneven fusion of the bones that make the skull (cranium). This affects the shape of the head and face, which may cause the two sides to appear unequal. The eyelids are droopy; the eyes widely spaced. The disorder is also associated with minor birth defects of the hands and feet. In addition, some individuals have mild intellectual disability. Some individuals with Saethre-Chotzen syndrome may require some medical or surgical intervention.

Description

Saethre-Chotzen (say-thre chote-zen) syndrome belongs to a group of rare genetic disorders with craniosynostosis. Craniosynostosis means there is premature closure of the sutures (seams) between certain bones of the cranium. This causes the shape of the head to be tall, asymmetric, or otherwise altered in shape (acrocephaly). There is also webbing (syndactyly) of certain fingers and toes. Another name for Saethre-Chotzen syndrome is acrocephalosyndactyly type III. It is one of the more mild craniosynostosis syndromes.

The story of Saethre-Chotzen syndrome goes back to the early 1930s. It was then that a Norwegian psychiatrist, Haakon Saethre, wrote about a mother and two daughters in the medical literature. Each had a low frontal hairline; long and uneven facial features; short fingers; and webbing of the second and third fingers and second, third, and fourth toes. A year later in 1931, F. Chotzen, a German psychiatrist, reported a family with similar features. However, these individuals were also quite short and had additional features of mild intellectual disability and hearing loss.

Genetic profile

Mutations in the *TWIST1* gene, located on the short (p) arm of chromosome 7 at position 21.2, cause Saethre-Chotzen syndrome. It is an autosomal dominant disorder and can be inherited, and passed on, by men as well as women. Almost all genes come in pairs. One copy of each pair of genes is inherited from the father and the other copy of each pair of genes is inherited from the mother. Therefore, if a parent carries a gene mutation for Saethre-Chotzen, each of his or her children has a 50% chance of inheriting the gene mutation. Each child also has a 50% chance of inheriting the working copy of the gene, in which case they would not have Saethre-Chotzen syndrome.

The search for the gene for Saethre-Chotzen syndrome is an interesting story. The first clue as to the cause of the disorder came in 1986, with the identification of patients who had a chromosome deletion of the short arm of chromosome 7. Linkage studies in the early 1990s narrowed the region for this gene to a specific site, at 7p21. Then, in 1996, scientists at Johns Hopkins Children's Center began to study *TWIST1* as the candidate gene for Saethre-Chotzen syndrome because of earlier studies that showed how this gene works in the mouse.

The mouse *TWIST* gene normally works in forming the skeleton and muscle of the head, face, hands, and feet. Mice lacking both copies of the gene die before birth. Many have severe birth defects, including failure of the neural tube to close. They have an abnormal head and limb defects. However, mice with just one nonworking copy of the *TWIST* gene did not die. Closer examination of these mice showed that they had only minor hand, foot, and skull defects. The features were similar to those seen in Saethre-Chotzen syndrome.

It was also known that the mouse *TWIST* gene was located on chromosome 12 in mice, a location that corresponds to the short arm of chromosome 7 in humans. With this evidence, the researchers went on to map and isolate the human *TWIST1* gene on human chromosome

KEY TERMS

Acrocephaly—An abnormal cone shape of the head.

Chromosome deletion—A missing sequence of DNA or part of a chromosome.

Craniosynostosis—Premature, delayed, or otherwise abnormal closure of the sutures of the skull.

Cranium—The skeleton of the head, which includes all of the bones of the head except the mandible.

Exon—The expressed portion of a gene. The exons of genes are those portions that actually chemically code for the protein or polypeptide that the gene is responsible for producing.

Linkage—The association between separate DNA sequences (genes) located on the same chromosome.

Syndactyly—Webbing or fusion between the fingers or toes.

Transcription—The process by which genetic information on a strand of DNA is used to synthesize a strand of complementary RNA.

Transcription factor—A protein that works to activate the transcription of other genes.

7. They showed that this gene was in the same location that was missing in some individuals with Saethre-Chotzen. The *TWIST1* gene is a small gene, containing only two exons (coding regions). Upon searching for alterations (mutations) in this gene, they found five different types of mutations in affected individuals. Since none of these mutations were found in unaffected individuals, this was proof positive that the *TWIST1* gene was the cause of Saethre-Chotzen syndrome.

Scientists have also used animal models and the fruit fly *Drosophila* to study the function of the *TWIST1* gene. They have found that it takes two *TWIST1* protein molecules to combine together, in order to function as a transcription factor for DNA. The normal function of the *TWIST1* protein is to bind to the DNA helix at specific places. By doing so, it works to regulate which genes are activated or “turned on.” Most of the mutations identified in the *TWIST1* gene so far seem to interfere with how the protein product binds to DNA. In effect, other genes that would normally be activated during development of the embryo may in fact not be turned on.

More recent studies suggest that the *TWIST1* protein may induce the activation of genes in the fibroblast

growth factor receptor (FGFR) pathway. Mutations in the FGFR family of genes cause other conditions with craniosynostosis such as Crouzon syndrome. Crouzon syndrome, like Saethre-Chotzen syndrome, is a mild craniosynostosis disorder. There is much overlap in the features of the face and hands in each condition. In fact, some patients initially thought to have Saethre-Chotzen were given a new diagnosis of Crouzon syndrome after studying both the *TWIST1* and the *FGFR* genes for mutations.

In all, it is thought that the *TWIST1* protein most likely acts to turn on the *FGFR* genes. These genes, in turn, instruct various cells of the head, face, and limb structures to grow and differentiate. If the *TWIST1* gene or other genes of the FGFR pathway are altered, an individual will have one of the craniosynostosis syndromes.

Demographics

Saethre-Chotzen syndrome affects both males and females equally. It most likely occurs in every racial and ethnic group and is believed to be underdiagnosed. The estimated incidence of the syndrome is 1 in every 25,000 to 50,000 individuals, making it the most common of the craniosynostosis syndromes.

Signs and symptoms

The cranium is made up of three main sections. The three sections are the face, the base of the cranium, and the top and sides of the head. Most of the cranium assumes its permanent shape before birth. However, the bones that make up the top and side of the head are not fixed in place, and the seams between the bones (cranial sutures) remain open. This allows the top of the head to adjust in shape, as the unborn baby passes through the narrow birth canal during labor. After birth, the cranial sutures will close, most often within the first few years of life. The shape of the cranium is then complete.

In Saethre-Chotzen, the shape of the cranium is abnormally formed. The reason is that the coronal suture closes too early, sometimes even before birth. The coronal suture separates the two frontal bones (forehead) from the parietal bones (top of the head). If the early closure is unilateral or asymmetric, then the forehead and face will form unevenly, from one side to the other. This also forces the top of the head to become more pointed, almost tower-like. The forehead looks high and wide. The face will appear uneven on each side, especially in the area of the eyes and cheeks.

There is also less space for the normal features of the face to develop. For instance, the eye sockets are shallower, and the cheekbones are flat. This makes the eyes more prominent and spaced further apart than normal.

QUESTIONS TO ASK YOUR DOCTOR

- My friend's baby was just diagnosed with Saethre-Chotzen syndrome. How serious is this disease?
- Will the child survive to adulthood, or is death at an early age likely?
- What are the characteristic symptoms of this disorder?
- Will the child have to remain under medical care throughout life?

Adding to the unevenness of the face is drooping of the upper eyelids, and a slight down-slant to the eyes. The nose may look beaked or bent slightly downward at the tip. In some individuals, the ears look small and low-set on the face.

The other main feature of the syndrome is minor abnormalities of the hands and feet. Webbing (syndactyly) commonly occurs between the second and third fingers and toes. The thumbs are short and flat. The fifth finger may be permanently curved or bent at the tip.

Each individual with Saethre-Chotzen is affected somewhat differently. The features are usually quite variable even within the same family. Most individuals are mildly affected. Their facial features may be somewhat flat and uneven, but not strikingly so. However, if more than one cranial suture closes too early (and this can happen in some individuals), there is more severe disfigurement to their face.

In addition to the physical characteristics, individuals with Saethre-Chotzen may have growth delays, leading to less than average adult height. Most individuals are of normal intelligence, although some may have mild to moderate intellectual disability (IQ from 50–70). For the growth and mental delays, it becomes necessary to provide special assistance and anticipatory guidance.

Diagnosis

For many years, there was widespread discussion among physicians (geneticists) over whether a given patient would have either Saethre-Chotzen or Crouzon syndrome. There may even be confusion with other craniosynostosis syndromes or with isolated craniosynostosis. However, the availability of direct gene testing now allows for a more definitive diagnosis for these patients. Simply using a blood sample, a direct gene test for

mutations in the *TWIST1* gene can be done. If an individual also has intellectual disability or other significant birth defects, it is suggested that they be screened more fully for deletions of the *TWIST1* gene.

Treatment and management

Very often, the physical characteristics of Saethre-Chotzen are so mild that no surgical treatment is necessary. The facial appearance tends to improve as the child grows. However, sometimes surgery is needed to correct the early fusion of the cranial bones. A specialized craniofacial medical team, experienced with these types of patients, should do this surgery. Surgery may also be done to release the webbing of the fingers and toes.

Some of the more severely affected individuals with Saethre-Chotzen may experience problems with their vision. There may be less space in the eye socket due to the bone abnormalities of the face. This can lead to damage of the nerves of the eye and may require corrective surgery. The tear ducts of the eye can also be missing or abnormal. Reconstructive surgery is sometimes performed to correct the drooping of the eyelids or narrowing of the nasal passage.

Prognosis

Most individuals with Saethre-Chotzen syndrome appear to have a normal lifespan.

Schinzel-Giedion syndrome

Definition

Schinzel-Giedion syndrome, or Schinzel-Giedion midface-retraction syndrome, is a rare malformation syndrome characterized by skeletal anomalies, a coarse face, urogenital defects, and severe intellectual disability.

Description

In affected individuals, the ureter, or tube that carries urine from the kidney into the bladder, is obstructed, causing the pelvis and kidney duct to become swollen with excess urine. This is called hydronephrosis. Other features of the syndrome include hypertrichosis or the excessive growth of hair, a flat midface, abnormal brain activity, skeletal abnormalities, and severe mental impairment.

Patients show abnormal bone maturation including broad and dense ribs and short arms and legs. Severely delayed mental and motor development is accompanied by seizures and spasticity.

Genetic profile

Some scientists have suggested that the syndrome is inherited as an autosomal recessive trait because they

KEY TERMS

Hydronephrosis—Obstruction of the tube that carries urine from the kidney into the bladder causing the pelvis and kidney duct to become swollen with excess urine.

observed that the syndrome appeared in two sibs of different sex, which suggested autosomal recessive inheritance. However, other researchers have hypothesized that Schinzel-Giedion syndrome may be a dominant disorder with gonadal mosaicism in one parent. Gonadal mosaicism can occur when either the testes or ovaries contain some cells with an extra chromosome. Scientists have also postulated that the syndrome may be caused by an unbalanced structural chromosome abnormality.

Demographics

Schinzel-Giedion syndrome is extremely rare, and the exact prevalence remains unknown. About 25 to 30 well-documented cases have been reported, beginning in 1978. The syndrome was originally observed in a brother who lived less than 24 hours and a sister who survived for 16 months. Both displayed multiple skull abnormalities and profound midface retraction. They each had congenital heart defects, hydronephrosis, clubfoot, and hypertrichosis. Eight other cases, all sporadic, including two offspring of consanguineous parents, were subsequently identified that year. Fewer than 30 cases are described in the medical literature detailing major and minor features of the syndrome. Only one case has been described in Japan. The other described cases have occurred in Western countries.

Signs and symptoms

Clinical signs include a flat midface, low-set ears, a prominent forehead, skull abnormalities including large fontanels or openings, a short broad neck, genital malformations, congenital heart defects including atrial septal defect, clubfoot, and growth retardation.

Diagnosis

The detection of renal defects using prenatal ultrasound is one of the primary means of diagnosis. Clinical observation of coarse facial features, skeletal anomalies, and MRI studies aid diagnosis after birth. Serial cranial MRI studies that show a progressive neurodegenerative process affecting both gray and white matter typify

QUESTIONS TO ASK YOUR DOCTOR

- What does the term “gonadal mosaicism” mean, and how is it related to Schinzel-Giedion syndrome?
- Are there tests by which this genetic disorder can be detected prenatally?
- What information can a genetic counselor provide my spouse and me about Schinzel-Giedion syndrome?
- What is the prognosis for a child born with Schinzel-Giedion?

Schinzel-Giedion syndrome. Clinical signs of abnormal cortical gray matter include seizures, dementia, and blindness in some cases. Abnormalities in the white matter can produce spasticity and hyperreflexia.

Treatment and management

MRI studies indicate the syndrome is a progressive neurodegenerative process and patients have a limited lifespan. Nursing care and supportive measures are required to keep the patient comfortable.

Prognosis

Death prior to the second year of life represents the most common outcome.

Julianne Remington

Schizophrenia

Definition

Schizophrenia is a psychotic disorder (or a group of disorders) marked by severely impaired thinking, emotions, and behaviors. Schizophrenic patients are typically unable to filter sensory stimuli and may have enhanced perceptions of sounds, colors, and other features of their environment. Most schizophrenics, if untreated, gradually withdraw from interactions with other people and lose their ability to take care of personal needs and grooming.

Description

The course of schizophrenia in adults can be divided into three phases or stages. In the acute phase, the patient has an overt loss of contact with reality (psychotic episode) that requires intervention and treatment. In the second, or stabilization, phase, the initial psychotic symptoms have been brought under control but the patient is at risk for relapse if treatment is interrupted. In the third, or maintenance, phase, the patient is relatively stable and can be kept indefinitely on antipsychotic medications. Even in the maintenance phase, however, relapses are not unusual and patients do not always return to full functioning.

The term “schizophrenia” comes from two Greek words that mean “split mind.” Around 1908, a Swiss doctor named Eugen Bleuler described a splitting-apart of mental functions that he regarded as the central characteristic of schizophrenia.

Recently, some psychotherapists have begun to use a classification of schizophrenia based on two main types. People with type I, or positive, schizophrenia, have a rapid (acute) onset of symptoms and tend to respond well to drugs. They also tend to suffer more from the “positive” symptoms, such as delusions and hallucinations. People with type II, or negative, schizophrenia, are usually described as poorly adjusted before their schizophrenia slowly overtakes them. They have predominantly

Colored PET brain scans of a normal patient (top) and one with schizophrenia (bottom). (Wellcome/Science Source)

“negative” symptoms, such as withdrawal from others and a slowing of mental and physical reactions (psychomotor retardation).

The fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)* specified five subtypes of schizophrenia—paranoid, disorganized, catatonic, undifferentiated, and residual—but those have been removed from *DSM-5* due to their low reliability as diagnostic tools.

Schizoaffective disorder

A condition commonly diagnosed as schizophrenia is schizoaffective disorder. This relatively rare disorder is characterized by psychotic symptoms in a patient with a mood disorder, usually manic depression. The psychotic symptoms may or may not be present at the same time as the mood disorder. Another complicating factor, especially in younger patients, is that distinguishing between manic depression and schizophrenia can be difficult in adolescents, since psychotic features are common during manic episodes in this age group.

Genetic profile

The risk of schizophrenia among first-degree biological relatives is 10 times greater than that observed in the general population. Furthermore, the presence of the same disorder is higher in monozygotic twins (identical twins) than in dizygotic twins (fraternal, or nonidentical, twins). The research on adoption and identical twins also supports the notion that environmental factors are important, because not all relatives who have the disorder express it. There are several chromosomes and loci (specific locations on chromosomes that contain mutated genes) that have been identified. Recent research has

implicated chromosomal 11 translocations in both schizophrenia and manic depression. In addition, there are now mutations of several genes that are postulated to be involved in schizophrenia, including *DTNBPI*, *NRG1*, *DAO*, *DAOA*, and *RSG4*. The mode of inheritance is not yet clear either. Some researchers believe there is an autosomal recessive pattern, some an irregular dominant inheritance, and others a polygenic inheritance, especially considering the spectrum of clinical symptoms that occur within the population of schizophrenic patients. Research is actively ongoing to elucidate the causes, types, and variations of these mutations. Genome sequencing, genome-wide association studies, and the understanding of DNA methylation and the relationship between genes and promoters and expression of such may be able to provide important information about dysregulation of genes and schizophrenia in the future. Animal models are already being done to study the genetic link to schizophrenia.

Demographics

A number of studies indicate that about 1% of the world’s population is affected by schizophrenia, without regard to race, social class, level of education, or cultural influences (outcomes may vary from culture to culture, depending on the familial support of the patient). Most patients are diagnosed in their late teens or early 20s, but the symptoms of schizophrenia can emerge at any age in the life cycle. The male/female ratio in adults is about 1.2:1. Male patients typically have their first acute episode in their early 20s, while female patients are usually closer to age 30 when they are recognized with active symptoms.

Schizophrenia is rarely diagnosed in preadolescent children, although patients as young as five or six have been reported. Childhood schizophrenia is at the upper end of the spectrum of severity and shows a greater gender disparity. It affects 1 or 2 children in every 10,000; the male/female ratio is 2:1.

Signs and symptoms

One of the reasons for the ongoing difficulty in classifying schizophrenic disorders is an incomplete understanding of their causes. Since 1998, it has been thought that these disorders were the end result of a combination of genetic, neurobiological, and environmental causes. A leading neurobiological hypothesis looks at the connection between the disease and excessive levels of dopamine, a chemical (neurotransmitter) that transmits signals in the brain. The genetic factor in schizophrenia has been underscored by recent findings that first-degree biological relatives of schizophrenics

are 10 times as likely to develop the disorder as are members of the general population.

Prior to recent findings of abnormalities in the brain structure of schizophrenic patients, several generations of psychotherapists advanced a number of psychoanalytic and sociological theories about the origins of schizophrenia. These theories ranged from hypotheses about the patient's problems with anxiety or aggression to theories about stress reactions or interactions with disturbed parents. Psychosocial factors are now thought to influence the expression or severity of schizophrenia, rather than cause it directly.

Another hypothesis suggests that schizophrenia may be caused by a virus that attacks the hippocampus, a part of the brain that processes sense perceptions. Damage to the hippocampus would account for schizophrenic patients' vulnerability to sensory overload. Researchers are preparing to test antiviral medications on schizophrenics.

Patients with a possible diagnosis of schizophrenia are evaluated on the basis of a set or constellation of symptoms; there is no single symptom that is unique to schizophrenia. In 1959, the German psychiatrist Kurt Schneider proposed a list of so-called first-rank symptoms, which he regarded as diagnostic of the disorder. These symptoms include:

- delusions
- somatic hallucinations
- hearing voices commenting on the patient's behavior
- thought insertion or thought withdrawal

Somatic hallucinations refer to sensations or perceptions concerning body organs that have no known medical cause or reason, such as the notion that one's brain is radioactive. Thought insertion and/or withdrawal refers to delusions that an outside force (for example, the FBI, the CIA, Martians, etc.) has the power to put thoughts into one's mind or remove them.

The so-called positive symptoms of schizophrenia are those that represent an excessive or distorted version of normal functions. Positive symptoms include Schneider's first-rank symptoms as well as disorganized thought processes (reflected mainly in speech) and disorganized or catatonic behavior. Disorganized thought processes are marked by characteristics: looseness of association, in which the patient rambles from topic to topic in a disconnected way; tangentially, which means that the patient gives unrelated answers to questions; and "word salad," in which the patient's speech is so incoherent that it makes no grammatical or linguistic sense. Disorganized behavior means that the patient has difficulty with any type of purposeful or goal-oriented behavior, including

personal self-care or preparation of meals. Other forms of disorganized behavior may include dressing in odd or inappropriate ways, sexual self-stimulation in public, or agitated shouting or cursing.

The *DSM-5* definition of schizophrenia includes three so-called negative symptoms. They are called negative because they represent the lack or absence of behaviors. The negative symptoms that are considered diagnostic of schizophrenia are a lack of emotional response (affective flattening), poverty of speech, and absence of volition or will. In general, the negative symptoms are more difficult for doctors to evaluate than the positive symptoms.

Diagnosis

A doctor must make a diagnosis of schizophrenia on the basis of a standardized list of outwardly observable symptoms, not on the basis of internal psychological processes. There are no specific laboratory tests that can be used to diagnose schizophrenia. Researchers have, however, discovered that patients with schizophrenia have certain abnormalities in the structure and functioning of the brain compared to normal test subjects. These discoveries have been made with the help of imaging techniques, such as computed tomography (CT) scans.

When a psychiatrist assesses a patient for schizophrenia, physical conditions will be excluded that can cause abnormal thinking and some other behaviors associated with schizophrenia. These conditions include organic brain disorders (including traumatic injuries of the brain), temporal-lobe epilepsy, Wilson disease, Huntington's chorea, and encephalitis. Substance abuse disorders, especially amphetamine use, will need to be ruled out.

After ruling out organic disorders, the clinician will consider other psychiatric conditions that may include psychotic symptoms or symptoms resembling psychosis. These disorders include mood disorders with psychotic features; delusional disorder; dissociative disorder not otherwise specified (DDNOS), or multiple personality disorder; schizotypal, schizoid, or paranoid personality disorders; and atypical reactive disorders. In the past, many individuals were incorrectly diagnosed as schizophrenic. Patients who were diagnosed prior to the changes in categorization introduced by *DSM-IV* should have their diagnoses, and treatment, reevaluated. In children, the psychiatrist must distinguish between psychotic symptoms and a vivid fantasy life, and also identify learning problems or disorders. After other conditions have been ruled out, the patient must meet a set of criteria, including:

- Characteristic symptoms: The patient must have symptoms over the course of six months with two (or more) active symptoms during a one-month period: delusions;

KEY TERMS

Affective flattening—A loss or lack of emotional expressiveness; sometimes called blunted or restricted affect.

Akathisia—Agitated or restless movement, usually affecting the legs and accompanied by a sense of discomfort; a common side effect of neuroleptic medications.

Catatonic behavior—Behavior characterized by muscular tightness or rigidity and lack of response to the environment.

Delusion—A fixed, false belief that is resistant to reason or factual disproof.

Depot dosage—A form of medication that can be stored in the patient's body tissues for several days or weeks, thus minimizing the risk of the patient forgetting daily doses.

Dopamine receptor antagonists (DAs)—The older class of antipsychotic medications, also called neuroleptics, which primarily block the site on nerve cells that normally receive the brain chemical dopamine.

Dystonia—Painful involuntary muscle cramps or spasms.

Extrapyramidal symptoms (EPS)—A group of side effects associated with antipsychotic medications, including parkinsonism, akathisia, dystonia, and tardive dyskinesia.

First-rank symptoms—A set of symptoms designated by Kurt Schneider in 1959 as the most important diagnostic indicators of schizophrenia: delusions, hallucinations, thought insertion or removal, and thought broadcasting.

Hallucination—A sensory experience of something that does not exist outside the mind.

Huntington's chorea—A hereditary disease that typically appears in midlife, marked by gradual loss

of brain function and voluntary movement; some symptoms resemble those of schizophrenia.

Negative symptoms—Symptoms of schizophrenia characterized by the absence or elimination of certain behaviors: affective flattening, poverty of speech, and loss of will or initiative.

Neuroleptic—Another name for the older type of antipsychotic medications given to schizophrenic patients.

Parkinsonism—A set of symptoms originally associated with Parkinson's disease that can occur as side effects of neuroleptic medications: trembling of the fingers or hands, a shuffling gait, and tight or rigid muscles.

Positive symptoms—Symptoms of schizophrenia that are characterized by the production or presence of behaviors that are grossly abnormal or excessive, including hallucinations and thought-process disorder.

Poverty of speech—A negative symptom of schizophrenia, characterized by brief and empty replies to questions.

Psychotic disorder—A mental disorder characterized by delusions, hallucinations, or other symptoms of lack of contact with reality.

Serotonin dopamine antagonists (SDAs)—The newer second-generation antipsychotic drugs, also called atypical antipsychotics, including clozapine (Clozaril), risperidone (Risperdal), and olanzapine (Zyprexa).

Wilson disease—A rare hereditary disease marked by high levels of copper deposits in the brain and liver.

Word salad—Speech that is so disorganized that it makes no linguistic or grammatical sense.

hallucinations; disorganized speech; disorganized or catatonic behavior; negative symptoms.

- The patient must show a decline in social, interpersonal, or occupational functioning, including self-care.
- Duration: The disturbed behavior must last for at least six months.
- Diagnostic exclusions: Mood disorders, substance abuse disorders, medical conditions, and developmental disorders have been ruled out.

Treatment and management

The treatment of schizophrenia depends in part on the patient's stage or phase. Patients in the acute phase are hospitalized in most cases, to prevent harm to the patient or others and to begin treatment with antipsychotic medications. A patient having a first psychotic episode should be given a CT or magnetic resonance imaging (MRI) scan to rule out structural brain disease.

The primary form of treatment of schizophrenia is antipsychotic medication. Antipsychotic drugs help to

control almost all the positive symptoms of the disorder. They have minimal effects on disorganized behavior and negative symptoms. Between 60% and 70% of schizophrenics will respond to antipsychotics. In the acute phase of the illness, patients are usually given medications by mouth or by intramuscular injection. After the patient has been stabilized, the antipsychotic drug may be given in a long-acting form called a depot dose. Depot medications last two to four weeks; they have the advantage of protecting the patient against the consequences of forgetting or skipping daily doses. In addition, some patients who do not respond to oral neuroleptics have better results with depot form. Patients whose long-term treatment includes depot medications are introduced to the depot form gradually during their stabilization period. Most people with schizophrenia are kept on antipsychotic medications indefinitely during the maintenance phase of their disorder to minimize the possibility of relapse.

The most frequently used antipsychotics have fallen into two classes: the older dopamine receptor antagonists, or DAs, and the newer serotonin dopamine antagonists, or SDAs. (Antagonists block the action of some other substance; for example, dopamine antagonists counteract the action of dopamine.) The exact mechanisms of action of these medications are not known, but it is thought that they lower the patient's sensitivity to sensory stimuli and so indirectly improve the patient's ability to interact with others.

The DAs include the older antipsychotic (also called neuroleptic) drugs, such as haloperidol (Haldol), chlorpromazine (Thorazine), and fluphenazine (Prolixin). These drugs have two major drawbacks: it is often difficult to find the best dosage level for the individual patient, and a dosage level high enough to control psychotic symptoms frequently produces extrapyramidal side effects, or EPS. EPS include parkinsonism, in which the patient cannot walk normally and usually develops a tremor; dystonia, or painful muscle spasms of the head, tongue, or neck; and akathisia, or restlessness. A type of long-term EPS is tardive dyskinesia, which features slow, rhythmic, automatic movements. Schizophrenics with AIDS are especially vulnerable to developing EPS.

The SDAs, also called atypical antipsychotics, are newer medications that include clozapine (Clozaril), risperidone (Risperdal), and olanzapine (Zyprexa). The SDAs have a better effect on the negative symptoms of schizophrenia than do the older drugs and are less likely to produce EPS than the older compounds. The newer drugs are significantly more expensive in the short term, although the SDAs may reduce long-term costs by reducing the need for hospitalization. They are also presently unavailable in injectable forms. The SDAs are commonly used to treat patients who respond poorly to the DAs. However, many psychotherapists now regard the use of

these atypical antipsychotics as the treatment of first choice.

Most schizophrenics can benefit from psychotherapy once their acute symptoms have been brought under control by antipsychotic medication. Psychoanalytic approaches are not recommended. Cognitive-behavioral therapy (CBT), however, is often helpful in assisting patients to acquire skills for daily living and social interaction. It can be combined with occupational therapy to prepare the patient for eventual employment.

Nutritional advancements have also been made for the management of schizophrenia. Vitamins and minerals important for brain health have been successful in the management of schizophrenia and its symptoms, including but not limited to omegas, vitamin D, B vitamins, serine, alanine, melatonin, choline, and antioxidants, among others. An anti-inflammatory-type diet may also be helpful in the management of schizophrenia.

Family therapy is often recommended for the families of schizophrenic patients, to relieve the feelings of guilt that they often have as well as to help them understand the patient's disorder. The family's attitude and behaviors toward the patient are key factors in minimizing relapses (i.e., reducing stress in the patient's life), and family therapy can often strengthen the family's ability to cope with the stresses caused by the schizophrenic's illness. Family therapy focused on communication skills and problem-solving strategies is particularly helpful. In addition to formal treatment, many families benefit from support groups and similar mutual help organizations for relatives of schizophrenics.

Prognosis

One important prognostic sign is the patient's age at onset of psychotic symptoms. Patients with early onset of schizophrenia are more often male, have a lower level of functioning prior to onset, a higher rate of brain abnormalities, more noticeable negative symptoms, and worse outcomes. Patients with later onset are more likely to be female, with fewer brain abnormalities and thought impairment, and more hopeful prognoses. Recent research has indicated that schizophrenia should be approached as a neurodevelopmental disorder and has even gone as far as saying that focuses on the abnormal development of the brain leading to schizophrenia could prove instrumental in the prevention of the early stages of schizophrenia. Prevention and early detection are key to the treatment and therefore the prognosis of schizophrenia.

The average course and outcome for schizophrenics are less favorable than those for most other mental disorders, although as many as 30% of patients diagnosed with schizophrenia recover completely and the majority do

QUESTIONS TO ASK YOUR DOCTOR

- Is schizophrenia always a genetic-based disorder, or are there other causes for the condition?
- What are the probabilities that my child will inherit schizophrenia from my spouse, who has the disorder?
- What kinds of treatment are available for dealing with schizophrenia, and how effective are those treatments?
- What factors determine the prognosis for a person with schizophrenia and, based on my spouse's current status, what is his prognosis for the disease?

experience some improvement. Two factors that influence outcomes are stressful life events and a hostile or emotionally intense family environment. Schizophrenics with a high number of stressful changes in their lives, or who have frequent contacts with critical or emotionally overinvolved family members, are more likely to relapse. Overall, the most important component of long-term care of schizophrenic patients is complying with their regimen of antipsychotic medications.

Schwartz-Jampel syndrome

Definition

Schwartz-Jampel syndrome (SJS) is a rare, inherited condition of the skeletal and muscle systems that causes short stature, joint limitations, and particular facial features.

Description

First described in 1962, SJS is now a clearly defined syndrome that is divided into two types. Type 1A is the classical form that develops in early childhood, usually between the first and third year of life. Type 1B is less common but more severe and its symptoms are present at birth. Both types of SJS involve generalized disease of the muscles called myopathy. The muscles tend to be quite stiff and are unable to relax normally. This is a condition known as myotonia. The myotonia causes many joints in the body to stay in a bent or flexed position (joint contractures).

In addition to muscle problems, the bones in the skeleton do not develop normally and this is why SJS may also be called a type of skeletal dysplasia. Abnormal bone shape and poor bone growth result in decreased total height, incorrect arm and leg postures, as well as curving of the spine (scoliosis).

Owen Howkins, a boy with Schwartz-Jampel syndrome, has become inseparable with his dog, Haatchi, who has proven to be a natural helper. (AP Images/Rex Features)

Unique facial features of SJS include narrow eye openings with drooping eye lids, a small mouth, and puckered lips. These features are also due to the stiffness of the muscles that support the face and individuals with SJS appear to have a fixed facial expression.

Persons affected with SJS often have normal intelligence, although varying degrees of intellectual disability may affect as many as 25% of patients. However, the myotonia may lead to poor speech articulation and drooling so that affected individuals are sometimes misdiagnosed as having intellectual disability.

Respiratory and feeding difficulties are frequent with SJS Type 1B due to the more severe nature of the muscle and bone disease. These problems may be fatal in early infancy. Persons with SJS Type 1A have a much longer life expectancy, although this depends on how their disease progresses.

SJS has also been referred to as:

- myotonic myopathy, dwarfism, chondrodystrophy, and ocular and facial abnormalities
- Schwartz-Jampel–Aberfeld syndrome

- Schwartz syndrome
- Aberfeld syndrome
- chondrodystrophic myotonia
- osteochondromuscular dystrophy
- spondylo-epimetaphyseal dysplasia with myotonia

Genetic profile

Both types of SJS are known to be inherited in an autosomal recessive manner. This was concluded after the following observations were made. SJS affects males and females alike. Parents of affected individuals rarely show any signs or symptoms of SJS. Parents have been reported to have more than one affected child. Consanguineous relationships were seen in some families.

Genetic studies of many families revealed that all cases of SJS were linked to an area on chromosome 1, described as 1p36.1. A gene in this region, heparan sulfate proteoglycan 2 (*HSPG2*), makes a protein called perlecan that plays an important role in maintaining cell membranes of the body's connective tissue (bone, cartilage, muscles, ligaments, tendons, and blood vessels).

Studies have shown that perlecan helps keep cartilage and bone strong and is essential for certain chemical processes in muscle tissues. It is also thought that perlecan helps to regulate the normal growth of some cells.

Mutations in the *HSPG2* gene have been found in some persons with SJS. These gene mutations change how the perlecan protein is made and usually prevent it from doing its normal job in the muscles and bones of the body.

The location 1p36.1 means that the gene is near the top or end of the short arm of chromosome number one. Human beings have 23 pairs of chromosomes in nearly every cell of their bodies. One of each kind (23 total) is inherited from the mother and another of each kind (23 total) is inherited from the father, for a total of 46. One chromosome may hold hundreds to thousands of individual genes and as the chromosomes exist in pairs, so do the genes. Therefore, every person has two copies of the *HSPG2* gene that makes perlecan. Individuals that have a diagnosis of SJS are thought to have a mutation in both copies of their *HSPG2* gene, each of which was inherited from one of their parents. Unaffected parents of children with SJS are therefore carriers for SJS. Their one normal *HSPG2* gene appears to make enough perlecan so those carriers do not show any symptoms of SJS. Most parents do not know that they are carriers for SJS until they have an affected child. When both parents are carriers for the same autosomal recessive disease such as SJS, there is a 25% chance with each and every pregnancy that they have together that their child will inherit both mutated *HSPG2* genes and develop SJS.

Demographics

SJS is a very rare genetic syndrome reported to affect males and females. It was initially described in the United States, but has also been reported in other countries. However, the exact incidence is unknown as no significant information is available on racial or sexual distribution.

Signs and symptoms

A child born with SJS Type 1A may show no outward signs of the condition at birth. Over the following one to three years, progressive myotonia of the muscles and resulting joint contractures develop. The typical bone problems become obvious and growth in height slows down. These symptoms are evident at birth in children with SJS Type 1B. The following descriptions apply to both SJS Type 1A and SJS Type 1B. However, each person with SJS may be affected to a different degree and their kinds of symptoms may vary.

Head and neck

Myotonia of the muscles in the face causes a tight and fixed facial expression. The eye openings are almost always narrowed and small and the upper and lower eyelids are not joined properly at the corners of the eye (blepharophimosis). The upper eyelid may also appear droopy (ptosis). Nearsightedness (myopia) is present in 50% of patients and occasionally cataracts and lens dislocation may develop in the eye. The mouth is small and the lips are puckered due to tight facial muscles. This may lead to speech difficulty. The chin may also be small or set back.

Body

Hernias of the groin and navel area are often noticed at birth. A hernia is the bulging of a tissue outside of its normal space and a simple operation can usually place it back inside. *Pectus carinatum* is a common bony deformity of the chest that causes the breast bone to protrude forward. Abnormalities in the growth and development of the bones of the spinal column (vertebrae) lead to scoliosis that usually worsens with age. Development of puberty is most often normal for persons with SJS.

Limbs

Some babies with SJS are born with a dislocation of their hip joint. This is common in infants without SJS as well. As the muscle disease of SJS progresses, the joints become very stiff. The hips, knees, and elbows in particular have very limited range of motion. These joint contractures worsen until puberty and then tend to stay the same from that point on. Eventually, a wheelchair is needed due to significant limitation of movement. The long bones in the body (e.g., the thigh bone) are bowed and shortened. This can cause a person with SJS to waddle as they walk and to stand in a crouching position. Therefore, an individual with SJS tends to be shorter than 90% of unaffected persons their age. A few have been reported to reach average height. Typically, their arms and legs have an increased amount of body hair as well.

Muscles

The muscles of the body show progressive myotonia, as they remain tight and are unable to relax normally. The muscle bulk may be increased in some areas, such as the thighs, and may waste away in others. As the muscles are unable to function normally, physical activity is restricted and a person may tire very easily.

Central nervous system and behavior

Most individuals with SJS have normal intelligence, although some degree of intellectual disability has been

KEY TERMS

Blepharophimosis—A small eye opening without fusion of the upper eyelid with the lower eyelid at the inner and outer corner of the eye.

Consanguineous—Sharing a common bloodline or ancestor.

Contracture—A tightening of muscles that prevents normal movement of the associated limb or other body part.

Myopathy—Any abnormal condition or disease of the muscle.

Myotonia—The inability to normally relax a muscle after contracting or tightening it.

reported. Developmental language problems and attention difficulties have also been seen in some cases. Reflexes tend to be slower than normal. A high-pitched voice and drooling may be noticed due to muscle stiffness in the mouth and throat area. This may cause feeding difficulties and choking may be of concern.

Diagnosis

The diagnosis of SJS Type 1A or Type 1B is made mainly by the presence of the symptoms described above. There is no specific biochemical or muscle testing that confirms a suspected diagnosis. Although research studies have identified mutations in the *HSPG2* gene in some families, widespread genetic testing is not clinically available. Such genetic mutations may be unique to each family and therefore may not be found in other persons affected with SJS.

Several different studies may be performed to determine the type and severity of muscle disease when considering a diagnosis of SJS. This may include a muscle biopsy that samples a piece of muscle and examines the appearance of the muscle cells. A muscle biopsy may appear normal or it may show signs of myopathy. A particular chemical, called creatine kinase, can be measured in a person's blood. Very high levels of creatine kinase usually indicate the presence of muscle disease or wasting. An electromyogram (EMG) is a test that measures the electrical currents made within an active muscle. The EMG pattern is usually abnormal in persons with SJS. These tests will confirm the presence of muscle disease but there are no specific changes in any of them that are unique to SJS.

The following are some abnormalities of the bones that are frequently noticed on x-rays:

- flat and irregularly formed vertebrae
- deformity of the upper part of the thigh bone
- a flattened joint socket where the hip and thigh bone meet
- specific changes in the development of the bones in the hand
- bowing of the long bones, especially the leg bones
- curvature of the spine that causes a hunchback appearance

Many of the symptoms of SJS are also present in other conditions, and it is important to distinguish SJS from the following disorders:

- Stuve-Wiedemann syndrome (which was previously called SJS type 2)
- Freeman-Sheldon syndrome (also known as whistling face syndrome)
- Marden-Walker syndrome
- Kniest dysplasia
- Seckel syndrome
- myotonic dystrophy
- the mucopolysaccharidoses

Treatment and management

There is not a cure for SJS. The treatment involves managing the symptoms of the condition as they develop and supporting the needs of the individual as the disability progresses. Several medical specialists may monitor a person with SJS for particular symptoms or complications. An orthopedic doctor manages the abnormal bone development and may offer surgical options for treatment of hip dislocation, scoliosis, or bone curvature. An ophthalmologist monitors eye problems such as nearsightedness and cataracts, for which glasses and surgery may be available. Cosmetic repair of blepharophimosis by plastic surgery may also be considered.

For those with a mental deficiency, special-education programs with options for activities in regular classrooms may offer the best opportunities for learning. Physical therapy may help maintain the greatest possible range of motion of the joints and speech therapy may improve speech problems due to a small and tight mouth. Physical activities of children are usually limited due to their stiff joints. As the condition progresses, persons with SJS are often wheelchair-bound by their teenage years and occupational therapy may help improve their everyday living skills. Adults who live independently may require some assistance with everyday tasks that their disability prevents them from doing, such as household chores or even bathing.

QUESTIONS TO ASK YOUR DOCTOR

- How do the two major types of Schwartz-Jampel syndrome differ from each other?
- What is the life expectancy of a person with each type of this disorder?
- What kinds of medical treatments are needed for each type of Schwartz-Jampel syndrome?

Prognosis

Individuals with SJS can live well into adulthood despite progressive disability but the average life expectancy is unclear. They are usually wheelchair-bound by their teenage or young adult years. Although puberty development may be normal, no reports have been made of an individual with SJS fathering children or carrying a pregnancy.

SJS Type 1B may be fatal in the newborn period due to serious respiratory and feeding problems. As the muscles in the face and neck may be very tight, it can be difficult to place a tube down the throat (intubation) to allow a baby to breathe. Feeding may be a continuous struggle due to problems with or an inability to swallow.

Both types of SJS cause persons to be more prone to develop chest infections and pneumonia. There is also an increased risk for complications from anesthesia, specifically malignant hyperthermia (MH). MH is an abnormal chemical reaction in the body to the use of some anesthesia medications. It causes high fevers, breathing difficulty, rigid muscles, and general serious illness. This condition may be life threatening.

Scleroderma

Definition

Scleroderma is a progressive disease that affects the skin and connective tissue, including cartilage, bone, fat, and the tissue that supports the nerves and blood vessels throughout the body. There are two major forms of the disorder: localized scleroderma, which mainly affects the skin, and systemic scleroderma, or systemic sclerosis, which affects the smaller blood vessels and internal organs of the body.

Description

Scleroderma is an autoimmune disorder characterized by the hardening of the skin. In scleroderma, there is an overproduction of abnormal collagen as it accumulates throughout the body, causing hardening (sclerosis), scarring (fibrosis), and other damage. The damage may affect the appearance of the skin, or in more severe cases it may also affect internal organs. The symptoms and severity of scleroderma vary from person to person.

Genetic profile

The role of genetics in the transmission of scleroderma is unclear, although mutations in the human leukocyte antigen (HLA) play a role in some cases of the disease. Some cases clearly run in families, but most

Line of hardened skin on the forehead in a teenaged female patient with linear scleroderma. Scleroderma is a chronic autoimmune disease characterized by a hardening of the skin, in this case in an isolated region. (Dr. Harout Tanielian/ Science Source)

occur in people without any family history of the disease. In 2021, research has linked new candidate genes to several aspects of scleroderma pathology that might help explain the disease's complexity at the molecular level. Gene expression, which is regulated by biological factors such as expression quantitative trait loci (eQTLs), affect cell activity. By identifying eQTLs that turn cells on or off in tissues most affected by scleroderma, investigators can begin to identify targeted therapies.

Demographics

Scleroderma occurs in all races of people, all over the world, but it affects about four females for every male. Among children, localized scleroderma is more common, and systemic sclerosis is comparatively rare. Most patients with systemic sclerosis are diagnosed between ages 30 and 50. Scleroderma occurs in about 20 people per million in the United States. Young African American women and Native Americans of the Choctaw tribe have especially high rates of the disease. Exact incidence is difficult to determine.

Signs and symptoms

The cause of scleroderma is still uncertain, although the accumulation of collagen appears to be a hallmark of the disease. Some theories suggest that damage to blood vessels may cause the tissues of the body to receive an inadequate amount of oxygen—a condition called ischemia. Some research suggests that the resulting damage causes the immune system to over-react and leads to an autoimmune response. Cells in the immune system called antibodies react to the body's own tissues as if they were foreign pathogens. The antibodies turn against the

already-damaged blood vessels and supporting tissues. These immune cells are designed to deliver potent chemicals in order to kill foreign invaders, and when some of these chemicals are delivered to the body's own tissues instead, the results include inflammation, swelling, damage, and scarring.

Most cases of scleroderma have no recognizable triggering event. Some cases, however, have been traced to exposure to toxic or poisonous substances. For example, coal miners and gold miners who are exposed to high levels of silica dust have above-average rates of scleroderma. Other chemicals associated with the disease include polyvinyl chloride, benzene, toluene, and epoxy resins. In 1981, 20,000 people in Spain were stricken with a syndrome similar to scleroderma when their cooking oil was accidentally contaminated. Certain medications, especially a drug used in cancer treatment called bleomycin (Blenoxane), may lead to scleroderma. Women with silicone breast implants have made some claims of a scleroderma-like illness, but a link has not been proven in scientific studies.

Symptoms of systemic scleroderma

A condition called Raynaud's phenomenon is the first symptom in about 95% of all patients with systemic scleroderma. Raynaud's phenomenon is characterized by the blood vessels of the fingers and/or toes reacting to cold in an abnormal way. The vessels clamp down, preventing blood flow to the tips of the digits. Eventually, the flow is cut off to entire fingers or toes, and over time oxygen deprivation may result in open ulcers on the skin surface. These ulcers can lead to tissue death (gangrene) and loss of digits. When Raynaud's phenomenon is the first sign of scleroderma the next symptoms usually appear within two years.

SKIN AND EXTREMITIES. Sclerosis of the skin can lead to swelling underneath the skin of the hands, feet, legs, arms, and face. This swelling can, in turn, contribute to the thickening and tightening of the skin, which becomes taut and shiny. Severe tightening may promote physical abnormalities, such as the fingers becoming permanently curled or flexed, structures within the skin getting damaged (e.g., the production of hair, oil, and sweat), and the skin becoming dry and scaly. Ulcers may form and lead to infection, and calcium deposits often appear under the skin.

As the skin on the face tightens, the mouth and nose may become smaller, which may interfere with eating and dental hygiene. Blood vessels under the skin may become enlarged and show through the skin, appearing as purplish marks or red spots. This chronic dilation of the small blood vessels is called telangiectasis.

Muscle weakness, joint pain and stiffness, and carpal tunnel syndrome are common in scleroderma. Carpal tunnel syndrome involves scarring in the wrist, which puts pressure on the median nerve running through that area. Pressure on the nerve causes numbness, tingling, and weakness in some of the fingers.

DIGESTIVE TRACT. The esophagus connects the mouth to the stomach and can become stiff and scarred in more serious cases of scleroderma. Patients may have trouble swallowing food, and the acid contents of the stomach may start to flow backward into the esophagus, causing it to become inflamed, a condition known colloquially as heartburn.

The intestines can become sluggish in processing food, causing bloating and pain, which can lead to foods not being digested properly, in turn resulting in diarrhea, weight loss, and anemia. Telangiectasis in the stomach or intestine may cause rupture and bleeding.

RESPIRATORY AND CIRCULATORY SYSTEMS. The lungs are affected in about 66% of all people with systemic scleroderma. Complications include shortness of breath, coughing, difficulty breathing due to tightening

of the tissue around the chest, inflammation of the air sacs in the lungs (alveolitis), increased risk of pneumonia, and an increased risk of cancer. For these reasons, lung disease is the most likely cause of death associated with scleroderma.

The lining around the heart (pericardium) may become inflamed in some cases of systemic scleroderma. The heart may have greater difficulty pumping blood effectively, thus causing irregular heart rhythms and enlargement of the heart.

Kidney disease is another common complication. The kidneys may stop filtering blood and go into failure. Damage to blood vessels in the kidneys often causes a major rise in the person's blood pressure. The blood pressure may be so high that there is swelling of the brain, causing severe headaches, damage to the retinas of the eyes, seizures, and failure of the heart to pump blood into the body's circulatory system. Treatments for high blood pressure have greatly improved these kidney complications. Before these treatments were available, kidney problems were the most common causes of death for people with scleroderma.

Scleroderma results in thickening and toughening of the skin, which may also become inflamed. (Dr. P. Marazzi/Science Source)

Other problems associated with scleroderma include painful dryness of the eyes and mouth, enlargement and destruction of the liver, and a low-functioning thyroid gland.

Diagnosis

Diagnosis of scleroderma is complicated by the fact that some of its symptoms can accompany other connective-tissue diseases. The most important symptom is thickened or hardened skin on the fingers, hands, forearms, or face, which is found in 98% of people with scleroderma and can be detected in the course of a physical examination. The person's medical history may also reveal important clues, such as exposure to toxic substances.

There are a number of nonspecific laboratory blood tests that may indicate the presence of an inflammatory disorder but not specifically scleroderma. The antinuclear antibody (ANA) test is positive in more than 95% of people with scleroderma and can be used to help confirm a diagnosis.

Other tests can be performed to evaluate the extent of the disease. They include a test of the electrical system of the heart (an electrocardiogram), lung-function tests, and x-ray studies of the gastrointestinal tract. Various blood tests can be given to study kidney function. Biomarkers can help assess risk for severe complications. One example is vasohibin-1, which is likely linked to the disease process; measuring levels of the protein could help determine a patient's risk for pulmonary fibrosis. A computer algorithm called DETECT has correctly identified patients with pulmonary arterial hypertension, a sometimes-fatal complication of scleroderma. If the test proves accurate for early detection, doctors can treat pulmonary arterial hypertension before it becomes critical.

Treatment and management

At this time, there is no cure for scleroderma. A drug called D-penicillamine has been used to interfere with the abnormal collagen production that is characteristic to scleroderma. It is thought to help decrease the degree of skin thickening and tightening and to slow the progress of the disease in other organs. Taking vitamin D and using ultraviolet light may be helpful in treating localized scleroderma. Corticosteroids have been used to treat joint pain, muscle cramps, and other symptoms of inflammation. Other drugs have been studied that reduce the activity of the immune system (immunosuppressants), but because these medications can have serious side effects, they are used in only the most severe cases of scleroderma.

KEY TERMS

Autoimmune disorder—A disorder in which the body's immune cells mistake its own tissues as foreign invaders; the immune cells then work to destroy tissues in the body.

Collagen—The main supportive matrix protein of cartilage, connective tissue, tendon, skin, and bone.

Connective tissue—A group of tissues responsible for support throughout the body, including cartilage, bone, fat, organs, blood vessels, and nerves.

Fibrosis—The abnormal development of fibrous tissue; scarring.

Limited scleroderma—A subtype of systemic scleroderma with limited skin involvement. It is sometimes called the CREST form of scleroderma, after the initials of its five major symptoms.

Localized scleroderma—Thickening of the skin from overproduction of collagen.

Morphea—The most common form of localized scleroderma.

Raynaud's phenomenon/Raynaud's disease—A condition in which blood flow to tissues is reduced by a malfunction of the nerves that regulate the constriction of blood vessels. When attacks of Raynaud's occur in the absence of other medical conditions, it is called Raynaud's disease. When attacks occur as part of a disease, as in scleroderma, it is called Raynaud's phenomenon.

Sclerosis—Hardening.

Systemic sclerosis—A rare disorder that causes thickening and scarring of multiple organ systems.

Telangiectasis—Very small arteriovenous malformations or connections between the arteries and veins. The result is red spots on the skin known colloquially as "spider veins."

The various symptoms of scleroderma are often treated individually. Raynaud's phenomenon requires that people try to keep their hands and feet warm constantly, and nifedipine is a medication that is also sometimes given to help control this symptom. Thick ointments and creams are used to treat dry skin. Exercise and massage may help joint involvement, and they may also help people retain more movement despite skin tightening. Skin ulcers need prompt attention and may require antibiotics.

People with esophageal reflux will be advised to eat small amounts more often rather than three large meals

QUESTIONS TO ASK YOUR DOCTOR

- What type of scleroderma do I have?
- How do we know that scleroderma is a genetic disorder?
- Am I likely to transmit scleroderma to any children that I may have in the future?
- Are there resources on the Internet from which I can get additional information about my scleroderma?

per day. They also should avoid spicy foods and items containing caffeine. Some patients with esophageal reflux have been treated successfully with surgery. Acid-reducing medications may be given for heartburn.

People with scleroderma must be monitored for the development of high blood pressure, and if that is found, they should be promptly treated with appropriate medications, usually ACE inhibitors or other vasodilators. When fluid accumulates due to heart failure, diuretics are prescribed to treat the accumulation of excess fluid. Lung disease also is possible, and a 2021 report showed possible treatment of lung problems in patients with scleroderma with tocilizumab, an anti-inflammatory drug used to treat rheumatoid arthritis. Detecting possible lung involvement early can improve the chance that the drug will help.

Another 2021 study demonstrated the possible use of fat grafts using the patient's own fat enhanced with adipose-derived skin cells to improve treatment of localized facial scleroderma by ensuring that the autologous fat graft survives longer.

Prognosis

The prognosis for people with scleroderma varies, depending on the severity of their condition. Some have a very mild form of the disease, called morphea, which affects only the skin, and these individuals have a very good prognosis. Others have a subtype of mild systemic scleroderma, called limited scleroderma. Limited involvement of the patient's skin and a cluster of five symptoms, called the CREST syndrome, characterize limited scleroderma. CREST stands for:

- C = Calcinosis
- R = Raynaud's disease (phenomenon)
- E = Esophageal dysmotility (stiffness and malfunctioning of the esophagus)

- S = Sclerodactyly (thick, hard, rigid skin over the fingers)
- T = Telangiectasis

In general, people with very widespread skin involvement have the worst prognosis. This level of disease is usually accompanied by involvement of other organs and the most severe complications. Although women are more commonly stricken with scleroderma, men more often die of the disease. The most common causes of death include heart, kidney, and lung diseases. About 65% of all patients survive 10 years or more following a diagnosis of scleroderma.

There are no known ways to prevent scleroderma. People can try to decrease occupational exposure to high-risk substances, however.

Sclerosing bone dysplasias

Definition

Sclerosing bone dysplasias are rare genetic disorders characterized by the creation of abnormally dense and overgrown bones. The abnormal bone formation in sclerosing bone dysplasias is caused by a defect in the replacement of old bone with new bone.

Description

Bone consists of living cells, called osteocytes, embedded in a calcium carbonate matrix that makes up the main bone material. The calcium carbonate matrix includes inorganic mineral components like calcium and organic components, such as collagen. The replacement of old bone with new bone is mediated by two types of bone cells: osteoblasts and osteoclasts. The osteoblasts make bone, while osteoclasts resorb, or take away, bone. Problems with the ability of the osteoclasts and osteoblasts to remodel bone can result in the increased skeletal density (sclerosis) and bony overgrowth (hyperostosis) seen in the sclerosing bone dysplasias. The first description of sclerosing bone dysplasia occurred in 1904 when Professor Albers-Schönberg of Hamburg described a patient suffering from a benign form of thickened and very strong hard bone.

Currently, sclerosing bone dysplasias are subdivided into types based upon the problems in bone remodeling. The three main categories of sclerosing bone dysplasias are increased bone density without modification of bone shape; increased bone density with involvement of the main body of the bone and primary region of bone formation (diaphysis); and increased bone density with involvement of the area of the developing long bone that is the growing portion of the bone (metaphysis). Although all of the sclerosing bone dysplasias share some overlapping

features, it is usually possible to distinguish between these types of sclerosing bone dysplasias based on the age at which symptoms appear, the pattern of inheritance in the family, radiographic skeletal surveys, and genetic studies.

Genetic profile

Although all of the genes involved in sclerosing bone dysplasias encode proteins that direct the remodeling of bone, each type of sclerosing bone dysplasia has specific symptoms and inheritance patterns caused by different gene defects.

Many types of sclerosing bone dysplasia are autosomal dominant genetic disorders. In autosomal dominant genetic disorders, the genes that cause a particular disorder are carried on one of the 22 pairs of numbered autosomal chromosomes, rather than on the X or Y sex chromosomes. In the case of sclerosing bone dysplasia, only one copy of the mutated, or nonworking, gene is necessary for the development of the disorder. An individual who inherits a normal gene copy from one parent and an abnormal gene copy from the other parent is likely to have symptoms of a sclerosing bone dysplasia. The children of an individual with one normal gene copy and one mutated copy have a 50% chance of inheriting the disorder. Types of sclerosing bone dysplasias inherited in an autosomal dominant pattern include osteopetrosis, autosomal dominant 1 and 2 (caused by mutations in over 12 different genes); progressive diaphyseal dysplasia/Camurati-Engelmann disease (caused by a mutation in the beta-1 transforming growth factor gene, *TGFBI*); some forms of craniodiaphyseal dysplasia; and some forms of craniometaphyseal dysplasia (caused by a mutation in a progressive ankylosis protein homolog, *ANKH*).

Many other types of sclerosing bone dysplasias are inherited in an autosomal recessive pattern. In an autosomal recessive condition, two copies of the mutated gene are needed to develop the symptoms of the disorder. In these cases, both parents each carry one copy of a mutated gene. Individuals with only one copy of a mutated gene for a recessive condition are known as carriers and have no symptoms related to the condition. In fact, every person carries between five and 10 mutated genes for harmful, recessive conditions. However, when two people with the same mutated recessive gene for sclerosing bone dysplasia have children together, there is a 25% chance with each pregnancy for the child to inherit two mutated copies, one from each parent. That child then has no working copies of the gene and will display the signs and symptoms associated with sclerosing bone dysplasia. Sclerosing bone dysplasias that are inherited in an autosomal recessive manner include osteopetrosis,

autosomal recessive (types 1, 2, 3, 4, 5, 6, 7, and 8) caused by mutations in at least 28 different genes; pycnodysostosis (caused by mutations in the cathepsin K gene, *CTSK*); some forms of craniodiaphyseal dysplasia, van Buchem disease, and sclerosteosis (all caused by a mutation in the sclerostin gene, *SOST*); and some forms of craniometaphyseal dysplasia caused by a mutation in the *GJAI* gene.

One type of sclerosing bone dysplasia, frontometaphyseal dysplasia, is caused by a mutation in the filamin A gene (*FLNA*) and is inherited in an X-linked recessive pattern. As opposed to genes that are carried on one of the 22 pairs of numbered autosomal chromosomes, X-linked genes are found on the sex chromosomes called X. Females have two X chromosomes, while males have a single X chromosome and a single Y chromosome. When a female inherits a mutated gene on the X chromosome, she is known as a carrier. Carriers most often have no symptoms related to the condition because the gene on her other chromosome continues to function properly. However, males only inherit one copy of the information stored on the X chromosome. When a male inherits a mutated copy of the gene that causes an X-linked recessive condition, he will experience the symptoms associated with the disease. The chance for a carrier female to have an affected son is 50%, while the chance to have a daughter who is also a carrier for the condition is 50%. An affected male has a 100% chance of having carrier daughters and a 0% chance of having affected sons.

One type of sclerosing bone dysplasia, osteopathia striata with cranial sclerosis, is caused by mutations in the *WTX* gene located on the X chromosome. This condition is inherited in an X-linked dominant pattern. X-linked dominant inheritance occurs when the gene mutation is located on the X chromosome, but the gene acts in a dominant manner. This means that both males and females can display the trait or disorder, while having only one copy of the gene. Furthermore, in X-linked dominant conditions, only one copy of the mutated gene is necessary for the development of the disorder. Therefore, an individual who inherits a normal gene copy from one parent and an abnormal gene copy for sclerosing bone dysplasia from the other parent is likely to have symptoms of sclerosing bone dysplasia. The children of an individual with one normal gene copy and one mutated copy have a 50% chance of inheriting a mutated sclerosing bone dysplasia gene.

Demographics

Sclerosing bone dysplasias are rare conditions. Estimates of general population frequency range by ethnic group and type of sclerosing bone dysplasia described. Affected individuals can occur within a variety of ethnic

backgrounds and cases have been found in Denmark, Egypt, the United States, Germany, Japan, Italy, Brazil, Spain, Senegal, South Africa, the Netherlands, and Cyprus. A large number of individuals affected by sclerosing bone dysplasias exist in the Afrikaner population of South Africa and the Dutch population of the Netherlands. The carrier rate for the single founder-derived mutation that causes sclerosteosis in the Afrikaner population is approximately 1 in 100. Van Buchem disease has been recognized predominantly in the Dutch population (± 20 cases). Several of the affected families have ancestral origins on the former island of Urk in the Zuider Zee. The prevalence of later-onset osteopetrosis or Albers-Schonberg is about 1 in 18,000 in Denmark.

Signs and symptoms

Sclerosing bone dysplasias are rare genetic disorders characterized by increased skeletal density and excessive bone formation, or overgrowth, due to a defect in the method of replacing old bone with new bone (bone remodeling). Each of the three main categories of sclerosing bone dysplasias exhibit different symptoms, including age of onset, skeletal involvement, and prognosis.

The specific disorders in the group of sclerosing bone dysplasias that exhibits increased bone density without modification of bone shape include osteopetrosis disorders (autosomal dominant osteopetrosis types I and II and autosomal recessive osteopetrosis); pycnodysostosis; and osteopathia striata with cranial sclerosis.

The osteopetrosis disorders are conditions that involve increased bone density without modification of bone shape. They include two dominant conditions known as osteopetrosis, autosomal dominant 1 and osteopetrosis, autosomal dominant 2, and one form of the recessive form of osteopetrosis, type 1.

Autosomal dominant osteoporosis, types 1 and 2 typically present in childhood, adolescence, or young adult life with multiple fractures, mild anomalies in head and face proportions, mild anemia, hearing loss, bone inflammation/infection, or increased bone density found on routine x-ray studies.

Autosomal dominant osteopetrosis type I (OPTA1) is characterized by a generalized increase in the hardness, thickness, and density of bone tissue (osteosclerosis), most pronounced in the cranial vault. Patients are often asymptomatic, but some suffer from pain and hearing loss. OPTA1 appears to be the only type of osteopetrosis not associated with an increased fracture rate.

Autosomal dominant osteopetrosis type II (OPTA2) is characterized by an increase in the hardness, thickness, and density of bone tissue (sclerosis), predominantly involving the spine, the pelvis, and the skull base.

Fragility of bones and dental abscesses are the leading complications. Other symptoms include arthritis of the hip (hip osteoarthritis), bone infections (osteomyelitis), thoracic or lumbar scoliosis, and cranial nerve involvement responsible for hearing loss, bilateral optic atrophy, and/or facial palsy.

Osteopetrosis, autosomal recessive 1 (OPTB1) is characterized by a generalized increase in bone density found at or soon after birth. The sclerosis of the bones causes a decrease in size of the bone marrow cavities, a progressively enlarging spleen, low blood iron (anemia), and blood cell production that occurs in other parts of the body (extramedullary haemopoiesis). Additionally, enlarging skull bones compress the optic nerves, auditory nerves, facial nerves, and the foramen magnum (the large hole at the base of the skull that allows passage of the spinal cord). The most frequent presentations in infancy are seizures, low calcium level, convulsions, failure of visual fixation (nystagmus), large spleen and liver (hepatosplenomegaly), and frequent broken bones.

Pycnodysostosis is characterized by an increase in bone density of the skeleton (osteosclerosis), skull deformities, short stature, short limbs, characteristic facial features, and bone fragility. Onset of the symptoms occurs around two or three years of age. Other features of the condition include separated cranial sutures; large fontanel with delayed closure; obtuse mandibular angle; delayed teeth eruption; enamel hypoplasia; dysplastic acromial ends of the clavicles; frontal bossing; ocular proptosis; and dysplastic nails.

Osteopathia striata with cranial sclerosis (OSCS) presents with longitudinal striations of dense bone in the long bones and formation of dense bone in the cranial and facial bones in infancy and childhood. The formation of dense bone in the head and face leads to facial disfigurement and to neurological complications, such as deafness due to pressure on cranial nerves. Other features include a large head (macrocephaly); congenital heart defects, such as aortic stenosis and ventricular septal defects; scoliosis of the back; narrowed visual fields; cleft palate; long fingers; curving of the third to fifth fingers (clinodactyly); clubfoot; facial nerve palsy; and mild mental retardation. Unfortunately most males with this condition die before delivery or shortly after birth. Males that do survive have short stature, intestinal abnormalities, and kidney defects.

The disorders involving increased bone density with diaphyseal involvement include progressive diaphyseal dysplasia, or Camurati-Engelmann disease; craniodiaphyseal dysplasia; and SOST-related sclerosing bone dysplasias (van Buchem disease and sclerosteosis).

Progressive diaphyseal dysplasia (PDD), or Camurati-Engelmann disease, is characterized by childhood onset of bone overgrowth (hyperostosis) and increased density (sclerosis) of the diaphyses of the long bones and the skull. Other features may include a slender build with long limbs; angular profile; prominent bones (asthenic habitus); hearing loss; protruding eyeballs (exophthalmos); optic nerve compression; double vision (diplopia); cavities (dental caries); sclerosis of skull base; lower jaw (mandible) involvement; sclerosis of posterior part of vertebrae (body and arches); scoliosis; progressive diaphyseal widening; thickened cortices; narrowing of medullary canal; Erlenmeyer flask defect of the bone; clubfoot (genu varus and valgus deformities); relative muscle weakness, especially in pelvic girdle; atrophic muscle fiber; headaches; delayed puberty; bone marrow hypoplasia; anemia; waddling gait; and leg pain. The most severely affected individuals will have progression of mild skull hyperostosis to severe skull thickening and cranial nerve compression over many years. Presentation of the disease can be very different from one individual to another.

Craniodiaphyseal dysplasia includes a wide variety of symptoms and age of onset from infancy to childhood. Facial and cranial thickening and distortion are particularly striking in this form. The characteristic facial features of craniodiaphyseal dysplasia occur from the overgrowth of bone in the face and skull that results in progressive facial anomalies, a broad nasal bridge, and wide-spaced eyes. Other symptoms of craniodiaphyseal dysplasia, like hearing loss and facial paralysis, are caused by the overgrowth of the skull as it gradually eliminates the perinasal sinuses and the large hole at the base of the skull that allows passage of the spinal cord (foramina of the skull base). Individuals with craniodiaphyseal dysplasia often are affected by mental retardation. Unlike the situation in the craniometaphyseal dysplasias, the long bones do not show metaphyseal flaring, but are shaped like a policeman's nightstick.

SOST-related sclerosing bone dysplasias include van Buchem disease and sclerosteosis as well as the autosomal dominant form of craniodiaphyseal dysplasia. Sclerosteosis and van Buchem disease include many similar features. The two disorders can be distinguished from each other via their different appearance of the bone changes on x-ray. Additionally, sclerosteosis includes the presence of asymmetric fusion (cutaneous syndactyly) of the index and middle fingers in many cases, and van Buchem disease does not.

Van Buchem disease (or hyperostosis corticalis familiaris) is characterized by progressive enlargement of the lower jaw in childhood and symptoms, including

KEY TERMS

Bone dysplasia—Abnormal bone development.

Bone remodeling—The process of breaking down old bone and building up new bone.

Bone sclerosis—Increased bone density and hardness.

Diaphysis—Primary region of ossification found in the shaft of the long bones.

Hyperostosis—Overgrowth of the bone.

Metaphysis—The growing portion of the developing long bone.

Osteoblasts—A bone cell that makes bone.

Osteoclasts—A bone cell that breaks down and reabsorbs bone.

hearing loss and facial paralysis, in adulthood caused by the overgrowth of the skull.

The symptoms of van Buchem disease begin in childhood or puberty and include features resulting from bone overgrowth. Symptoms include cranial bone overgrowth (hyperostosis) leading to optic nerve compression; hearing loss; headaches; cranial nerve palsy; osteosclerosis; thickened cortex of long bones; and abnormally high blood levels of phosphorous (hyperphosphatasemia).

Sclerosteosis is characterized by tall stature; overgrowth of the nasal and facial bones; broad, flat nasal bridge; wide-spaced eyes (hypertelorism); and minor hand malformation, such as finger fusion (syndactyly). Other symptoms may include small nails (nail dysplasia); square jaw due to overgrowth of the mandible; difficulties in chewing; inability to smell (anosmia); massive bone density (sclerosis) of the long tubular bones, ribs, pelvis, and skull; and multiple cranial nerve involvement resulting in optic atrophy, facial palsy, and trigeminal nerve pain episodes (neuralgia). Facial nerve paralysis may be present as early as birth or develop soon afterward. Facial palsy and deafness as a result of cranial nerve entrapment often develop in childhood. Increased intracranial pressure may result in sudden death from impaction of the brain stem in the foramen magnum.

The disorders involving increased bone density with metaphyseal involvement include craniometaphyseal dysplasia and frontometaphyseal dysplasia.

Craniometaphyseal dysplasia involves overgrowth bone anomalies that commonly present in infancy. Some of the first indications of craniometaphyseal dysplasia

include breathing difficulties and narrowing nasal passages due to bone overgrowth. The characteristic facial features of craniometaphyseal dysplasia occur from the overgrowth of bone in the face and skull that result in progressive facial anomalies, a broad nasal bridge, and wide-spaced eyes. Other symptoms of craniometaphyseal dysplasia, like hearing loss and facial paralysis, are caused by the overgrowth of the skull as it gradually eliminates the perinasal sinuses and the large hole at the base of the skull that allows passage of the spinal cord (foramina of the skull base). The features of craniometaphyseal dysplasia are more severe than the sclerotic or hyperostotic features, except in the lower jaw where they are less severe than craniodiaphyseal dysplasia. If not treated, individuals with craniometaphyseal dysplasia may develop blindness due to the compression of cranial nerves.

Frontometaphyseal dysplasia's most striking feature is a characteristic facial appearance that includes a very prominent supraorbital ridge above the eyes resulting from bone overgrowth. In many cases, the prominent ridge may be present at birth, along with a small, pointed chin, wide-spaced eyes (hypertelorism), wide nasal bridge, poor sinus development, clubfoot (coxa valga and genu valgum), and flared metaphyses. Later findings may include progressive mixed conductive and sensorineural hearing loss; high palate/cleft palate; teeth issues; mitral valve prolapse; narrow trachea; winged shoulder blade (scapulae); irregular rib contours; "coat hanger" deformity of lower ribs; distended kidneys and ureters (hydronephrosis and hydroureter); scoliosis; cervical vertebral fusion; flared pelvis; elbow contractures; knee and ankle contractures; Erlenmeyer-flask appearance of femur and tibia; increased density of long bone diaphyses; finger and wrist contractures; long and wide fingers; partial fusion of the bones of the feet; large feet; overgrowth of hair on the buttocks and thighs; and muscle wasting (especially legs and arms). The skeletal dysplasia and the associated clinical findings show significant variability from affected individual to individual. Females with frontometaphyseal dysplasia may also develop the same characteristic craniofacial appearances seen in the males, but they do not have many of the other characteristic features of this condition.

Diagnosis

Diagnosis of sclerosing bone dysplasias is most often based upon age of onset, clinical features, radiological evaluation, and family history. Radiologic examination will detect the dense bones (sclerosis) and their locations. Genetic studies may help confirm a diagnosis of a specific sclerosing bone dysplasia, but some affected individuals will not have a genetic mutation that can be

identified. While many types of sclerosing bone dysplasias have a known or suspected genetic cause, genetic testing is not always available because the gene has recently been discovered or the genetic cause is not yet fully understood.

Treatment and management

The sclerosing bone dysplasias are genetic disorders and do not have specific therapies that remove, cure, or fix all signs of the disorder. Treatment and management of the sclerosing bone dysplasias focus on treatment of specific symptoms of the condition. Management of patients with sclerosing bone dysplasias requires a comprehensive approach to characteristic clinical problems, including hematologic and metabolic abnormalities, fractures, bone deformities, back pain, bone pain, bone infection (osteomyelitis), hearing impairment, dental issues, short stature, and neurologic symptoms. Surgical intervention may be difficult and prolonged in affected individuals since standard equipment may be too short and not powerful enough to cut through the dense bone. In addition, bone regrowth occurs and may cause recurrence of symptoms after surgery.

Treatment of the hematologic issues found in the sclerosing bone dysplasias is focused on the correction of low blood iron (anemia) and low platelets. In some cases, a steroid, prednisone, may be used to treat both of these conditions. In other cases, transfusions to treat anemia and splenectomy to increase platelets may be recommended. Depending on the form of sclerosing bone dysplasia, treatment to correct hematologic issues may not be effective.

Medical treatment of sclerosis and hyperostosis in sclerosing bone dysplasias is based on efforts to stimulate host osteoclasts to break down bone or provide an alternative source of osteoclasts. Stimulation of osteoclasts has been attempted with calcium restriction and calcitriol, calcitonin therapy, steroids, parathyroid hormone therapy, and interferon. Bone marrow transplant has been used to treat infantile malignant osteopetrosis. Effective therapies for each type of sclerosing bone dysplasia need to be individualized. Many people affected by a sclerosing bone dysplasia will not respond to treatment.

Most treatment protocols for sclerosing bone dysplasias are focused upon the correction of the frequent bone fractures, using splints, casts, and braces. Orthopedic surgery may be needed to correct internal fractures.

Since hearing loss is a common feature of the sclerosing bone dysplasias, formal audiological evaluation is recommended at diagnosis. Hearing loss associated with the sclerosing bone dysplasias can be addressed through sign language, use of hearing aids, and/or surgery. Some

QUESTIONS TO ASK YOUR DOCTOR

- What type of sclerosing bone dysplasia do I/does my child have?
- Can you recommend the necessary surgical specialists to treat my condition?
- What is the chance to have another child affected with the same condition?
- Is genetic testing available for my form of sclerosing bone dysplasia?
- Will my child's/my lifespan be affected by this condition?

individuals pursue exploratory tympanotomy, stapedotomy, placement of a total ossicular reconstruction prosthesis, cochlear implantation, insertion of a Wehr's prosthesis, decompression, and other surgical procedures. Widening of the external auditory canal is usually necessary to accommodate a hearing aid. Correction of hearing loss is difficult and only has limited success.

In forms of sclerosing bone dysplasias associated with short stature, most individuals make an effort to modify their environment to suit their height. For individuals who wish to treat their short stature, some progress in increasing height has been made by growth hormone (GH) supplementation in affected children. However, hormone supplementation can cause disproportionate growth, leading to longer arms and trunk and shorter legs.

Intracranial pressure is one of the main features of sclerosing bone dysplasias, and the most severe. The increase in intracranial pressure caused by the increase in bone size and density often leads to headaches, hearing loss, blindness, facial paralysis, facial nerve palsies, and death. Accordingly, management of intracranial pressure includes monitoring for increased pressure, sudden onset of headaches, and blurred vision that may result in the need for decompression craniectomy or other forms of surgical decompression. Total decompression can prevent future attacks of facial paralysis in some forms of sclerosing bone dysplasias. Given the progressive nature of the sclerosing bone dysplasias, bone regrowth will occur and may cause recurrence of symptoms after surgery.

The abnormal formation of the head and skull bones impacts the form and function of the face, jaws, and remainder of the craniofacial skeleton. Surgery to correct bony overgrowth and density in the forehead, nose, and jaw bones is an option for some patients. Given the

progressive nature of the sclerosing bone dysplasias, bone regrowth will occur and may cause recurrence of symptoms after surgery.

The objective of treatment for bone infection (osteomyelitis) in sclerosing bone dysplasias is to eliminate the infection and prevent the development of chronic infection. Intravenous antibiotics are started early and may later be changed, depending on culture results. Some new antibiotics can be very effective when given orally. In chronic infection, surgical removal of dead bone tissue is usually necessary.

Treatment of scoliosis depends upon the type of sclerosing bone dysplasias and the severity of the scoliosis. Treatment options may include observation, orthoAbnormal bone development.pedic braces, and surgery. In some cases, the progressive nature of the underlying condition makes correction of scoliosis difficult, if not impossible.

The treatment for clubfoot involves orthopedic surgery to correct the abnormal formation of the lower limbs. Correction of the abnormality may require multiple surgeries, and aftercare with casts, braces, and physical therapy.

Treatment of the myriad of dental issues associated with sclerosing bone dysplasias are managed best through comprehensive oral and dental care. A craniofacial team may be best suited to address the variety of issues. Mandible reduction is often performed for cosmetic reasons or if mouth closure is impaired as a result of overgrowth of the mandible. Tooth extraction may be difficult given the density of bone.

Individuals affected by sclerosing bone dysplasias may have pain from arthritis, neuralgia caused by pressure, dental pain, and other pain sources related to abnormal bone remodeling. Pain management for each of these sources is different. Severe pain resulting from nerve compression may be helped by nerve decompression surgery. Spinal cord decompression surgery may help alleviate back pain. A pain management specialist working with an individual's treatment team can determine the level of pain, determine the best medications to treat the pain, and evaluate the effectiveness of the medications.

Prognosis

The prognosis for individuals affected by sclerosing bone dysplasia varies greatly depending upon the type of sclerosing bone dysplasia and severity of symptoms. Individuals affected by delayed or adult-onset forms of sclerosing bone dysplasia may have mild to severe symptoms that do not reduce their lifespan. Individuals who present with symptoms at birth or soon after birth, like

malignant infantile osteopetrosis and sclerosteosis, have a progressive course of disease that leads to early death. Increased intracranial pressure may result from a combination of circumstances and may have led, in several instances, to sudden death from impaction of the brain stem in the foramen magnum. Surgical procedures such as total decompression may increase length and quality of life.

Scoliosis

Definition

Scoliosis is a side-to-side curvature of the spine of 10 degrees or greater.

Description

When viewed from the rear, the spine usually appears to form a straight vertical line. Scoliosis is a lateral (side-to-side) curve in the spine, usually combined with a rotation of the vertebrae. The lateral curvature of scoliosis should not be confused with the normal set of front-to-back spinal curves visible from the side. While a small degree of lateral curvature does not cause any medical problems, larger curves can cause postural imbalance and lead to muscle fatigue and pain. More severe scoliosis can interfere with breathing and lead to arthritis of the spine (spondylosis).

Four out of five cases of scoliosis are *idiopathic*, meaning the cause is unknown. Children with idiopathic scoliosis appear to be otherwise entirely healthy and have not had any bone or joint disease early in life. Scoliosis is not caused by poor posture, diet, or carrying a heavy book bag exclusively on one shoulder.

Idiopathic scoliosis is further classified according to age of onset:

- **Infantile.** Curvature appears before age three. This type is quite rare in the United States, accounting for only 1% of idiopathic cases in North America, but is more common in Europe, where it is 4% of known idiopathic cases.
- **Juvenile.** Curvature appears between ages 3 and 10. This type may be equivalent to the adolescent type, except for the age of onset.
- **Adolescent.** Curvature appears between ages 10 and 13 near the beginning of puberty. This is the most common type of idiopathic scoliosis.
- **Adult.** Curvature begins after physical maturation is completed.

Causes are known for three other types of scoliosis:

- **Congenital scoliosis** is due to congenital birth defects in the spine, often associated with other structural abnormalities such as neural tube defects.
- **Neuromuscular scoliosis** is due to loss of control of the nerves or muscles that support the spine. The most common causes of this type of scoliosis are cerebral palsy and muscular dystrophy.

X-ray of a spine in a patient with scoliosis. (Tewan Banditrukkanka/Shutterstock)

- Degenerative scoliosis may be caused by degeneration of the discs that separate the vertebrae or arthritis in the joints that link them.

Genetic profile

Idiopathic scoliosis has long been observed to run in families. Twin and family studies have consistently indicated a genetic contribution to the condition. However, no consistent pattern of transmission has been observed in familial cases. Research published in 2014 suggests mutations in the following genes may contribute to idiopathic scoliosis: *POC5*, *TBX6*, and *SH3GL1*. While other data has shown that there may not be a genetic link to scoliosis via mutations of the *MESP2*, *HES7*, and *DUSP6* genes as previously suspected, an earlier study found data to suggest that a combination of genetic predisposition and fetal hypoxia may create the condition in which scoliosis may be triggered. However, no further data has been published to support this hypothesis. Examination of chromosomal anomalies in individuals with idiopathic scoliosis identified a duplication of chromosome 1q21.1 and rearrangements of chromosome 15q11.2 and 16p11.2, suggesting that copy number variation and chromosomal aneuploidy may contribute to the pathogenesis of adolescent idiopathic scoliosis.

There are several genetic syndromes that involve a predisposition to scoliosis, and several studies have

investigated whether or not the genes causing these syndromes may also be responsible for idiopathic scoliosis. Using this *candidate gene approach*, the genes responsible for Marfan syndrome (fibrillin), Stickler syndrome, and some forms of osteogenesis imperfecta (collagen types I and II) have not been shown to correlate with idiopathic scoliosis.

Attempts to map a gene or genes for scoliosis have not shown consistent linkage to a particular chromosome region. Most researchers have concluded that scoliosis is a complex trait. As such, there are likely to be multiple genetic, environmental, and potentially additional factors that contribute to the etiology of the condition. Complex traits are difficult to study due to the difficulty in identifying and isolating these multiple factors.

Demographics

The incidence of scoliosis in the general population is 2%–3%. Among adolescents, however, 10% have some degree of scoliosis (though less than 1% have curves that require treatment).

Scoliosis is found in both boys and girls, but a girl's spinal curve is much more likely to progress than a boy's. Girls require scoliosis treatment about five times as often. The reason for these differences is not known but may relate to increased levels of estrogen and other hormones.

Signs and symptoms

Scoliosis causes a noticeable asymmetry in the torso when viewed from the front or back. The first sign of scoliosis is often seen when a child is wearing a bathing suit or underwear. A child may appear to be standing with one shoulder higher than the other, or to have a tilt in the waistline. One shoulder blade may appear more prominent than the other due to rotation. In girls, one breast may appear higher than the other, or larger if rotation pushes that side forward.

Curve progression is greatest near the adolescent growth spurt. Scoliosis that begins early on is more likely to progress significantly than scoliosis that begins later in puberty.

More than 30 states have screening programs in schools for adolescent scoliosis, usually conducted by trained school nurses or gym teachers.

Diagnosis

Diagnosis for scoliosis is done by an orthopedist. A complete medical history is taken, including questions about family history of scoliosis. The physical examination includes determination of pubertal development in adolescents, a neurological exam (which may reveal a

KEY TERMS

Aneuploidy—The state of having an abnormal number of chromosomes.

Cobb angle—A measure of the curvature of scoliosis, determined by measurements made on x-rays.

Pathogenesis—The process by which biophysical and biochemical reactions cause disease.

Scoliometer—A tool for measuring trunk asymmetry; it includes a bubble level and angle measure.

Spondylosis—Arthritis of the spine.

neuromuscular cause), and measurements of trunk asymmetry. Examination of the trunk is done while the patient is standing, bending over, and lying down, and involves both visual inspection and use of a simple mechanical device called a scoliometer.

If a curve is detected, one or more x-rays will usually be taken to define the curve or curves more precisely. An x-ray is used to document spinal maturity, any pelvic tilt or hip asymmetry, and the location, extent, and degree of curvature. The curve is defined in terms of where it begins and ends, in which direction it bends, and by an angle measure known as the Cobb angle. The Cobb angle is found by projecting lines parallel to the vertebrae tops at the extremes of the curve; projecting perpendiculars from these lines; and measuring the angle of intersection. To properly track the progress of scoliosis, it is important to project from the same points of the spine each time.

Occasionally, magnetic resonance imaging (MRI) is used, primarily to look more closely at the condition of the spinal cord and nerve roots extending from it if neurological problems are suspected.

Treatment and management

Treatment decisions for scoliosis are based on the degree of curvature, the likelihood of significant progression, and the presence of pain, if any.

Curves less than 20 degrees are not usually treated, except by regular follow-up for children who are still growing. Watchful waiting is usually all that is required in adolescents with curves of 20–25 degrees, or adults with curves up to 40 degrees or slightly more, as long as there is no pain.

For children or adolescents whose curves progress to 25 degrees, and who have a year or more of growth left, bracing may be required. Bracing cannot correct

curvature, but may be effective in halting or slowing progression. Bracing is rarely used in adults, except where pain is significant and surgery is not an option, as in some elderly patients.

There are two different categories of braces, those designed for nearly 24-hour use and those designed for night use. The full-time brace styles are designed to hold the spine in a vertical position, while the night-use braces are designed to bend the spine in the direction opposite the curve.

The Milwaukee brace is a full-time brace that consists of metal uprights attached to pads at the hips, rib cage, and neck. Other types of full-time braces, such as the Boston brace, involve underarm rigid plastic molding to encircle the lower rib cage, abdomen, and hips. Because they can be worn out of sight beneath clothing, the underarm braces are better tolerated and often leads to better compliance. The Boston brace is currently the most commonly used. Full-time braces are often prescribed to be worn for 22–23 hours per day, though some clinicians believe that recommending brace use of 16 hours leads to better compliance and results.

Night-use braces bend the patient's scoliosis into a correct angle, and are prescribed for 8 hours of use during sleep. Some investigators have found that night-use braces are not as effective as the day-use types.

Bracing may be appropriate for scoliosis due to some types of neuromuscular disease, including spinal muscular atrophy, before growth is finished. Duchenne muscular dystrophy is not treated by bracing, since surgery is likely to be required, and since later surgery is complicated by loss of respiratory capacity.

Surgery for idiopathic scoliosis is usually recommended if:

- the curve has progressed despite bracing
- the curve is greater than 40–50 degrees before growth has stopped in an adolescent
- the curve is greater than 50 degrees and continues to increase in an adult
- there is significant pain

Orthopedic surgery for neuromuscular scoliosis is often done earlier. The goals of surgery are to correct the deformity as much as possible, to prevent further deformity, and to eliminate pain as much as possible. Surgery can usually correct 40%–50% of the curve, and sometimes as much as 80%. Surgery cannot always completely eliminate pain.

The surgical procedure for scoliosis is called *spinal fusion*, because the goal is to straighten the spine as much

QUESTIONS TO ASK YOUR DOCTOR

- How do the four types of scoliosis differ from each other?
- Can scoliosis be prevented and, if so, how?
- What kinds of treatment are available for scoliosis, and how successful is each type of treatment?
- How does scoliosis affect a person's lifespan or the quality of life for that person?

as possible, and then to fuse the vertebrae together to prevent further curvature. To achieve fusion, the involved vertebra are first exposed, and then scraped to promote regrowth. Bone chips are usually used to splint together the vertebrae to increase the likelihood of fusion. To maintain the proper spinal posture before fusion occurs, metal rods are inserted alongside the spine, and are attached to the vertebrae by hooks, screws, or wires. Fusion of the spine makes it rigid and resistant to further curvature. The metal rods are no longer needed once fusion is complete, but are rarely removed unless their presence leads to complications.

Spinal fusion leaves the involved portion of the spine permanently stiff and inflexible. While this leads to some loss of normal motion, most functional activities are not strongly affected, unless the very lowest portion of the spine (the lumbar region) is fused. Normal mobility, exercise, and even contact sports are usually all possible after spinal fusion. Full recovery takes approximately six months.

Prognosis

The prognosis for a person with scoliosis depends on many factors, including the age at which scoliosis begins and the treatment received. Most cases of mild adolescent idiopathic scoliosis need no treatment, do not progress, and do not cause pain or functional limitations. Untreated severe scoliosis often leads to spondylosis, and may impair breathing.

Seckel syndrome

Definition

Seckel syndrome is an extremely rare inherited recessive disorder characterized by low birth weight, dwarfism, a very small head, intellectual disability, and unusual characteristic facial features, including a "beak-like" protrusion of the nose, large eyes, a narrow face, low ears, and an unusually small jaw. Common signs also include abnormalities of bones in the arms and legs.

Description

Seckel syndrome is one of the microcephalic primordial dwarfism syndromes—a category of disorders characterized by profound growth delay. It is characterized by dwarfism, a small head, developmental delay, and intellectual disability and abnormalities may also be found in the cardiovascular, hematopoietic, endocrine, and central nervous systems. Children with the disorder are often hyperactive and easily distracted; about half have IQs below 50. Individuals with Seckel syndrome are able to live for an extended period of time.

Seckel syndrome is also known as "bird-headed dwarfism," Seckel-type dwarfism, and nanocephalic

KEY TERMS

Autosomal recessive disorder—A genetic disorder that requires two mutated forms of a gene to be inherited for the traits of a disorder to develop.

Microcephalic primordial dwarfism syndromes—A group of disorders characterized by profound growth delay and small head size.

dwarfism. The disorder was named after Helmut G.P. Seckel, a German pediatrician who came to the United States in 1936. Dr. Seckel did not discover the syndrome but he authored a publication describing the disorder's symptoms based on two of his patients.

Genetic profile

Seckel syndrome displays an autosomal recessive pattern of inheritance. This means that both parents of a child with the disorder carry a copy of the Seckel gene—but the parents appear entirely normal. When both parents carry a copy of the Seckel gene, their children face a one in four chance of developing the disorder.

There are eight types of Seckel syndrome, each linked to mutations in different genes within the genome. The first type is caused by a mutation in the ataxia-telangiectasia and Rad3-related protein (*ATR*) gene and is the best characterized. The *ATR* gene codes for a phosphatidylinositol 3-linked kinase protein, which is an enzyme involved in sensing DNA damage and controlling the cell cycle. It is possible that mutations in this gene affect how well cells can monitor and manage DNA damage during replication.

Demographics

Seckel syndrome is extremely rare and appears to affect both men and women equally. Between 1960—the year that Dr. Seckel defined the disorder—and 2005, more than 100 cases have been reported.

Signs and symptoms

Prenatal signs of Seckel syndrome include cranial abnormalities and intrauterine growth delays that result in low birth weight. Postnatal growth delays result in dwarfism. Other physical features associated with the disorder include a very small head, often more severely affected than even the height; abnormalities of bones in the arms and legs; malformation of the hips; a permanently bent fifth finger; failure of the

QUESTIONS TO ASK YOUR DOCTOR

- How common is Seckel syndrome and what groups, if any, are at special risk for the disorder?
- How is Seckel syndrome diagnosed?
- What information can a genetic counselor give me about Seckel syndrome?
- What organizations can I contact for additional information about Seckel syndrome?

testes to descend into the scrotum in males; and unusual characteristic facial features, including a “beak-like” protrusion of the nose, large eyes, a narrow face, low ears, and an unusually small jaw. Children with the disorder not only have a small head but also a smaller brain, which leads to developmental delay and intellectual disability. Seizures have also been reported in some cases.

Diagnosis

Several forms of primordial dwarfism exhibit characteristics similar to those of Seckel syndrome, and it can be challenging for physicians to differentiate true Seckel syndrome from other, similar dwarfisms. Physicians do have a set of primary diagnostic criteria to follow—the criteria were first defined by Dr. Seckel in 1960 and later revised in 1982 to prevent overdiagnosis of cases.

Most of the primary diagnostic features of Seckel syndrome, including severe intrauterine growth restriction, a small head, a characteristic “bird-like” face, and intellectual disability, are well suited for prenatal sonographic diagnosis. The use of ultrasound examinations to evaluate fetal growth and the careful evaluation of the fetal face and cranial anatomy has proven effective at detecting Seckel syndrome.

Treatment and management

There is no cure for Seckel syndrome but certain medications may be prescribed to address other symptoms associated with the disorder.

Prognosis

Children affected with Seckel syndrome can live for an extended period of time although they are often faced with profound mental and physical deficits.

Selfish gene theory

Definition

The selfish gene theory is a reinterpretation of the theory of natural selection from the standpoint of the genes within a genome. It postulates that there is an increased frequency of genes whose phenotypic effects in turn increase their replication success. Genes do this in cooperation with or to the detriment of other genes by building an organism that can effectively transmit them to future generations. The term “selfish gene” is the

popularized term for what is considered a gene-centered view on evolution.

Description

The selfish gene theory is a gene-centric rewriting of the theory of natural selection. In the original theory developed by Charles Darwin, evolution occurs when environmental pressures select for phenotypes or traits found within a population that provide a better reproductive benefit. Over several generations, these traits are preserved because they provide an advantage to those individuals within their environment. In other words, adaptations and genetic variance are the *phenotypic effects* of genes maximizing their heritable success. The selfish gene theory puts natural selection into a gene-centered perspective. It argues that adaptation happens by way of genes competing with each other such that those that produce phenotypic traits that promote their propagation increase their allelic frequency within a population. Ultimately, the theory states that evolution and natural selection act upon genes rather than populations of organisms because they inherit genetic information almost exclusively from DNA. The biologist Richard Dawkins developed the term and theory in 1976 as an extension of George C. Williams's book *Adaptation and Natural Selection*, which discussed altruism as a result of selection at the level of genes rather than on the level of a group. The selfish gene theory is used to investigate the possible genetic contributions to behavior, particularly altruism. It helps to postulate that altruism is, in part, a combination of kinship and recognition of shared phenotypes; in both cases preserving relatives or those with a similar trait has a positive cost-benefit ratio to the survival of common genes.

Along with contributing to the genetic understanding of altruistic behavior, the selfish gene theory also adds to the explanation of the existence of deceit, the preservation of characteristics that benefit the few at the cost of the population as a whole. In both cases, the passage of the gene over time through generations takes precedence over the transmission vehicle (i.e., the organism).

Applications of the selfish gene theory

Genetic combinations that help an organism survive or reproduce also improve a gene's own chances of being replicated. While this would classically be considered an outcome of natural selection on a population with genetic variation, gene-centric evolutionary theory interprets this as genetic success on the side of the gene, rather than reflecting on the benefit to the organism or the population.

KEY TERMS

Allele—One version of a gene that occurs at the same position (locus) on a chromosome.

Diploid—Having two copies of each gene within a genome.

Gamete—Reproductive cells of an organism that fuse together during fertilization.

Gene—The molecular unit of heredity. A gene is a specific sequence of DNA that is found at particular positions in the genome and codes for a particular protein product.

Genome—An organism's complete collection of genetic material.

Haploid—Having just one copy of each gene within a genome.

Intragenomic—Pertaining to components of one genome.

Locus—A specific position of a gene within a genome.

Meiosis—The process of cell division to produce haploid gametes.

Meiotic driver—A gene that affects or modifies the processes that control meiosis.

Natural selection—The evolutionary pressure that affects the survival and reproduction of individuals based on their differing phenotypes within a population.

Phenotype—The physical manifestation of the genetic composition of an organism.

Recombination—The production of genetic combinations in offspring that are different from those of the parents. This process occurs during meiosis.

As a matter of course, this requires that the reproduction or replication of a gene can be at the expense of the organism. The selfish gene theory is often utilized to postulate the molecular contributions to behavior that increases reproductive fitness over mortality, to rationalize the persistence of "junk DNA" within genomes that is not selected for but is nonetheless transmitted to future generations, and to explain intragenomic conflict and non-Mendelian genetic inheritance patterns.

Female meiotic drive

During meiosis in females, one functional egg and three non functional polar bodies are produced. Only genes that make it into the egg will be passed on to the next

generation, providing a condition for gene competition. Based on the Mendelian rule of random assortment, each genetic allele has a 50% chance of being passed on to the next generation; however, because only one egg is produced this chance is decreased. Female meiotic drive occurs when there is preferential segregation that favors the transmission of some genes over others.

Meiotic drivers are alleles that can increase their transmission frequency through the exploitation of the asymmetric cell division that occurs during meiosis. These genes are called “drivers” because they modify the rate of recombination during meiosis. Genetic recombination is a crucial part of providing genetic differences between parents and their offspring; it essentially scrambles the parental genome to create new allelic combinations in the next generation and can also affect inheritance rates of genes. If genes can modulate or alter the rate of recombination they can impact the potential of their inheritance. In this way, the ability to control recombination can be an evolutionary gain for meiotic drivers. Oftentimes this control comes at the expense of fertility in that organism. A recently discovered example of a meiotic driver in mice is the gene *r2d2* that is passed on to the next generation more than 50% of the time.

Intragenomic conflict

Female meiotic drive is an example of intragenomic conflict. This arises when genes in the same genome are not transmitted to the next generation with the same efficiency, especially when one gene inhibits the transmission or replication of another gene for its own replicative benefit.

Criticism

While Dawkins’s book *The Selfish Gene* and the gene-centric view of evolution have been and continue to be important in the theoretical investigation of biology and behavior, several scientists and philosophers have criticized the theories and their applications. Notably, Stephen Jay Gould, an influential evolutionary biologist, argued that genes cannot directly affect natural selection and that the selfish gene theory oversimplifies the relationship between genes and their organisms. Where Dawkins calls the gene the fundamental unit of selection, more traditional interpretations of evolution consider the phenotype to be the unit of selection because it is the relation of phenotypic variation and a population’s environment that allows for evolutionary pressure. In this view, genetic differences merely register the changes that occur with evolution—they do not cause evolutionary changes within a population. Biologist Niles Eldredge describes the argument as the difference between genes having a causal versus a passive recording role in evolution.

The gene-centric view of evolution conflicts with some population genetics models, and many critics suggest that from a sociobiological perspective, the selfish gene theory relies too heavily on animal behavior examples to describe human behavior models. Additionally, opponents state that there are moral and ethical issues with the theory in its description of altruistic behavior as an ultimately selfish response and that this justifies anti-social behavior or behavior that operates against communal benefit. Dawkins does, however, conclude that human intellect and free will can outweigh the genetic component of behavior.

Septo-optic dysplasia

Definition

Septo-optic dysplasia (SOD) is a rare congenital disorder that includes underdevelopment of the nerves at the back of the eye(s), absence of the septum pellucidum and/or corpus callosum in the brain, and dysfunction of the pituitary gland that produces hormones in the body.

Description

SOD is also known as DeMorsier’s syndrome and is commonly recognized as the association of three features: underdevelopment of the optic nerves (optic nerve hypoplasia), absence of midline structures of the brain (most often the septum pellucidum), and problems with the functioning of the pituitary gland in the brain that controls hormone production in the body. These three

Septo-optic dysplasia is a disorder that includes absence of a part of the brain called the septum pellucidum and/or corpus callosum. (Living Art Enterprises, LLC/Science Source)

features of SOD most often cause partial or complete blindness and mild to severe visual problems, difficulty with coordination of mental and muscular activities, such as walking, and short stature. Individuals with SOD may have normal intelligence, or learning problems that can range from mild to severe.

Genetic profile

Most often, SOD occurs sporadically and is not inherited. For most individuals with SOD, there is no family history of the condition. However, there have been a few familial cases reported. These families raise the possibility that there is a form of SOD that is inherited in an autosomal recessive pattern. In autosomal recessive inheritance, two unaffected parents both carry a mutation in a single copy of a gene for a condition. When both parents pass the mutated gene on to a child, the child with two copies of the gene mutation is affected with the condition. People who are related by blood are more likely to be carriers of mutations in the same gene since they inherit their genes from a common ancestor.

Mutations in a gene called *HESX1*, located on the upper short arm of chromosome 3, have been identified in some people with SOD. The brother and sister whose parents were related were both found to have mutations in both copies of their *HESX1* genes. A 2001 study of 228 individuals with SOD or features of SOD revealed that three had a mutation in one copy of their *HESX1* gene. One Japanese individual with features of SOD was also found to have a mutation in one copy of his

HESX1 gene. Therefore, it is likely that *HESX1* is fully or partially causative in a small subset of individuals with SOD. The product of the *HESX1* gene is expressed in the brain in early development and has been shown to be involved in the development of structures that give rise to the pituitary gland. In 1998, a strain was created in mice with mutations in the *HESX1* gene so that no product was made from the gene. These mice had features similar to individuals with SOD, including pituitary gland dysfunction as well as structural changes in the brain and eyes.

Other causes of SOD are thought to be related to viral infections, diabetes, antiseizure medications, alcohol, and illicit drug use during pregnancy. In addition, a 2004 study suggested that amniotic bands may be responsible for SOD in some patients. Amniotic bands are formed when the inner membrane of the sac holding the fluid around a fetus tears. Pieces of the amnion may wrap around various parts of the fetus and restrict blood flow to those areas. Limb malformations have been shown to be caused by amniotic bands in some cases. However, in 2004 it was suggested that limb malformations are a recurrent feature of SOD, rather than SOD being caused by amniotic bands.

Demographics

The condition is considered to be rare, with an estimated incidence of 1 in 10,000 people. SOD does not occur more often in males or females and is not known to occur more or less frequently in any racial or ethnic group. SOD may become apparent during infancy, childhood, or in adolescence.

Signs and symptoms

A variety of changes in the structure and function of the eye(s) can occur as part of SOD. Most commonly, individuals have optic nerve hypoplasia, meaning that the nerves from the back of the eye to the brain are underdeveloped. The nerves may be small, and there are usually far fewer nerves connecting the eye to the brain than usual. The optic disk (the front surface of the optic nerve) may also be smaller than usual. Infants with SOD may have rapid, involuntary eye movements called nystagmus. Other changes in the structure of the eye may occur, such as strabismus (the eyes cannot focus on the same object at the same time), coloboma (notch-like area of absent tissue), and microphthalmia (small openings of the eyes). The optic features of SOD may affect one or both eyes, so that an individual with the condition may have good vision in one eye, or may have decreased or no vision in both eyes.

There can also be a variety of structural changes to the brain in people with SOD. Most often, a membrane in the midline of the brain called the septum pellucidum is absent. This membrane separates the fluid-filled cavities on each side of the brain. Another midline structure, the corpus callosum, may also be absent or underdeveloped. The corpus callosum is the thick band of nerve fibers that connects the two hemispheres of the brain. In addition, the region of the brain that controls voluntary movement, the cerebellum, may be underdeveloped. Other structural brain malformations have been reported in individuals with SOD.

Additional structures in the brain that can be affected in individuals with SOD include the hypothalamus and the pituitary gland. These parts of the brain control the production and release of hormones in the body. Individuals with SOD may not produce enough growth hormone and may exhibit short stature. There may be problems with low blood sugar, dehydration, seizures, and the production of hormones needed for sexual development.

Various other conditions have been reported in individuals with SOD. These include cleft lip and/or palate; limb anomalies, including fusion of fingers or toes and underdevelopment of fingernails or toenails; and apnea (difficulty breathing).

Patients affected with SOD can present at any age depending on the severity of the symptoms. Signs and symptoms, including failure to thrive, prolonged jaundice (yellow color to the skin caused by extra amounts of bile in the blood), difficulty controlling body temperature, decreased blood sugar, small genitalia, or low muscle tone, can herald the diagnosis of SOD in newborns. Older children may complain of visual difficulties, or have the inability to fixate on an object.

Many individuals with SOD have normal intelligence. However, there is a range of intelligence reported, including those with mild learning delays and those with significant mental retardation. Learning delays and mental retardation may be the result of structural changes in the brain or hormone disorders. Unrecognized visual problems or lack of education appropriate for those with visual impairment may also cause learning delays.

Diagnosis

SOD is often suspected when a child with visual impairment also has growth delay. When a diagnosis of SOD is suspected, a person is referred to several specialists who each perform tests to verify the diagnosis. An ophthalmologist can perform vision testing and examinations of the structure of the eye for features of SOD. In individuals with SOD, the optic nerves appear small and gray or pale in color and can be surrounded by a double

KEY TERMS

Computerized tomography (CT)—A technique that uses a beam of radiation and a computerized analysis to produce an image of a body structure, often the brain.

Corpus callosum—A band of nerve fibers that connects the right and left hemispheres of the brain.

Magnetic resonance imaging (MRI)—A technique that uses a magnetic field to produce images of various body structures.

Mutation—A permanent change in the DNA code of a gene that disrupts the gene from making its product, such as a protein or enzyme.

Optic nerve—A nerve at the back of the eyes that conducts impulses that cause sight.

Pituitary gland—A gland at the base of the brain that controls hormone production in the body; the hormones produced by the pituitary gland control growth, reproduction, and other bodily processes.

Septum pellucidum—A membrane made of nerve tissue that separates areas of fluid in the left and right sides of the brain.

pigmented ring or margin. In addition, stimulation testing of the optic nerves can be performed. A neurologist (brain specialist) can perform imaging studies of the brain, such as magnetic resonance imaging (MRI) or computerized tomography (CT) scan of the brain, focusing on the visual pathways, the septum pellucidum, hypothalamus-pituitary region, and other midline structures. An endocrinologist can perform blood tests to determine if there are problems with various hormones in the body.

There has been a report of prenatal diagnosis of SOD by an ultrasound that revealed absence of the septum pellucidum. Subsequent blood and urine tests on the mother revealed low levels of the hormone estriol, indicating a problem with the fetal pituitary gland. The diagnosis was confirmed after birth.

Treatment and management

SOD is treated symptomatically. Vision may be improved with corrective lenses, surgery, or other treatment. Seizures may be controlled with medication. Hormone deficiencies are managed with hormone replacement therapy, such as growth hormones or thyroid supplements. Hormone problems may arise at different ages, so even if not present initially, a person with SOD should be followed by an endocrinologist over time.

Children with SOD should receive early assessments of learning and development so that any supportive therapies, such as physical, speech, or educational therapy, can be initiated. Children with SOD may benefit from an individualized educational plan (IEP) in school, which is a plan created by a child's teachers, therapists, and other individuals who have performed developmental testing and designed techniques best suited to the child's needs. Families may consider placing a child with SOD in a school for visually impaired children. The child's pediatrician can monitor a child for any special needs and refer additional specialists as needed. Individuals and families with SOD may benefit from talking with a genetic counselor about possible patterns of inheritance and recurrence risks for SOD in the family. Families should also be introduced to the appropriate local and national support organizations, such as the American Foundation for the Blind, for further help and assistance.

Prognosis

Prognosis is variable, depending on the number and severity of features present. Most individuals with SOD have significant visual impairment, and many are legally blind. Patients with severe visual impairment may have difficulty obtaining a driver's license or gainful employment. Lifespan is most often normal, however, cortisol deficiency can lead to life-threatening episodes brought about by infection or stress.

Severe combined immunodeficiency

Definition

Severe combined immunodeficiency (SCID) is a group of rare, life-threatening diseases present at birth that impair the immune system. Without a healthy immune system the body cannot fight infections and individuals can easily become seriously ill from common infections.

Description

SCID is considered to be the most severe of the 70 forms of primary immunodeficiency diseases (PID). Primary immunodeficiency diseases describe conditions where a component of the immune system—either an organ or cells of the immune system—are missing or defective in their functions. There is a wide spectrum in the severity of symptoms associated with PIDs.

SCID is also known as the "boy in the bubble" syndrome because living in a normal environment can be

Severe Combined Immunodeficiency: pedigree chart analysis (Gale)

fatal to those affected, requiring them to be contained in a controlled, clean environment. SCID initially was called Swiss agammaglobulinemia because it was first described in Switzerland in 1961. Any exposure to germs or pathogens can pose a risk for infection including bacterial, viral, and fungal infections. In the first few months of life children with SCID become very ill with infections such as pneumonia (infection of the lungs that prevents oxygen from reaching the blood, making breathing difficult), meningitis (infection of the covering of the brain and spinal cord), sepsis (infection in the bloodstream), and viruses. Such infections can be fatal within the first year of life due to their compromised immune system.

Children with SCID do not respond to medications like other children because their immune system does not function properly. They may also have an underdeveloped thymus gland. Medication usually stimulates a person's immune system to fight infection but in the case of SCID the immune system is unable to respond. The immune system is a complex network of cells and organs that protect the body from infection. The thymus and lymphatic system (lymph nodes and lymphatic vessels) house and transport two very important cells that fight infection called B and T cells. The bone marrow produces cells that become blood cells as well as cells that compose the immune system. One type of cell called lymphocytes, or white blood cells, mature in the bone marrow to form B cells, while others mature in the thymus to become T cells. B and T cells are the two major groups of lymphocytes that recognize and attack infections. Children with SCID have either abnormal or absent B and T cells.

Other infections can be seen in children with SCID including skin infections, yeast infections in the mouth and diaper area, diarrhea, and infection of the liver. Children with SCID fail to gain weight and grow normally. Treatment for SCID is available; however, many children with SCID are not diagnosed in time and die before their first birthday.

A diagnosis of SCID needs to be made quickly since common infections can prove fatal. In addition, permanent damage can result in the ears, lungs, and other organs.

Genetic profile

Genetic information is carried in tiny packages called chromosomes. Each chromosome contains thousands of genes and each gene contains the information for a specific trait. All human cells, except for cells involved in reproduction, contain 23 pairs of chromosomes for a total of 46 chromosomes. One of each pair of chromosomes is inherited from the mother and the other is inherited from the father. SCID is usually inherited in one of two ways: X-linked recessive or autosomal recessive. Recessive

X-Linked Severe Combined Immunodeficiency: pedigree chart analysis (Gale)

means that two copies of the gene are necessary to express the condition. Autosomal recessive means that the gene for the disease or trait is located on one of the first 22 pairs of chromosomes, or autosomes. Males and females are equally likely to have an autosomal recessive disease or trait. Therefore, a child inherits one copy of the gene from each parent, who is called a carrier because they have only one copy of the gene. Since carriers do not express the gene, parents usually do not know they carry the SCID gene until they have an affected child. Carrier parents have a 1-in-4 chance (or 25%), with each pregnancy to have a child with SCID.

The last pair of human chromosomes, either two X's (female) or one X and one Y (male)—determines gender. X-linked means the gene causing the disease or trait is located on the X chromosome. X-linked recessive diseases are most often seen in males because they only have one X chromosome. Therefore, if a male inherits a particular gene on the X chromosome, he expresses the gene because he only has a single copy of it. Females, on the other hand, have two X chromosomes and can carry a mutated gene on one of their X chromosomes yet not express any symptoms because their second X chromosome works normally. A mother usually carries the gene for SCID unknowingly and has a 50/50 chance with each pregnancy to transmit the gene. If the child is male, he will have SCID; if the child is female, she will be a carrier for SCID like the mother.

SCID is a group of inherited disorders caused by the inheritance of different mutated genes. About half of the cases are due to a gene on the X chromosome called *IL2RY*, which is important for proper immune cell development. The second most common form of SCID is

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman’s abdomen and into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Amniotic fluid—The fluid that surrounds a developing baby during pregnancy.

Autosomal recessive inheritance—A pattern of genetic inheritance where two abnormal genes are needed to display the trait or disease.

Bone marrow—A spongy tissue located in the hollow centers of certain bones, such as the skull and hip bones. Bone marrow is the site of blood cell generation.

Bone marrow transplant (BMT)—A medical procedure used to treat some diseases that arise from defective blood cell formation in the bone marrow. Healthy bone marrow is extracted from a donor to replace the marrow in an ailing individual. Proteins on the surface of bone marrow cells must be identical or very closely matched between a donor and the recipient.

Boy in the bubble—A description for SCID since these children need to be isolated from exposure to germs, until they are treated by bone marrow transplantation or other therapy.

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance a needle is inserted either through the mother’s vagina or abdominal wall and a sample of cells is collected from around the fetus. These cells are then tested for chromosome abnormalities or other genetic diseases.

Failure to thrive—Significantly reduced or delayed physical growth.

Gene therapy—Replacing a defective gene with a normal copy.

Immune system—A major system of the body that produces specialized cells and substances that interact with and destroy foreign antigens that invade the body.

Lymphatic system—Lymph nodes and lymphatic vessels that transport infection-fighting cells around the body.

Lymphocytes—Also called white blood cells, lymphocytes mature in the bone marrow to form B cells, which fight infection.

Meningitis—An infection of the covering of the brain and spinal cord.

Pneumonia—An infection of the lungs.

Primary immunodeficiency disease (PID)—A group of approximately 70 conditions that affect the normal functioning of the immune system.

Sepsis—An infection of the bloodstream.

Severe combined immunodeficiency (SCID)—A group of rare, life-threatening diseases present at birth that cause a child to have little or no immune system. As a result, the child’s body is unable to fight infections.

Sporadic—Isolated or appearing occasionally with no apparent pattern.

Thymus gland—An endocrine gland located in the front of the neck that houses and transports T cells, which help to fight infection.

X-linked recessive inheritance—The inheritance of a trait by the presence of a single gene on the X chromosome in a male, passed from a female who has the gene on one of her X chromosomes, who is referred to as an unaffected carrier.

responsible for 15% of the cases and is caused by a mutation in the gene *ADA*, which codes for adenosine deaminase, an enzyme required for lymphocyte proliferation. Lymphocytes are crucial for a functional immune system and without them the immune system is compromised. The remaining 35% of SCID cases are caused by either an unknown autosomal recessive gene or are the result of a new mutation. New mutations—alterations in the DNA of the gene—can cause disease. In these cases neither parent has the disease-causing mutation. This may occur

because the mutation in the gene happened for the first time only in the egg or sperm for that particular pregnancy. New mutations are thought to happen by chance and are therefore referred to as “sporadic,” meaning by chance.

Demographics

It is estimated that about 400 children a year are born with some type of primary immunodeficiency disease. Approximately 1 in 100,000 children are born with SCID

each year regardless of the part of the world the child is from or the ethnic background of the parents. This disease can affect both males and females depending on its mode of inheritance.

Signs and symptoms

Babies with SCID fail to thrive, are frail, and do not grow well. They have numerous and serious life-threatening infections that usually begin in the first few months of life. Because they do not respond to medications like other children they may be on antibiotics for one or two months with no improvement before a physician considers a diagnosis of SCID. The types of infections typically include chronic skin infections, yeast infections in the mouth and diaper area, diarrhea, infection of the liver, pneumonia, meningitis, and sepsis. They can also have serious sinus and ear infections, as well as a swollen abdomen. Sometimes deep abscesses occur, which are pockets of pus that form around infections in the skin or in the body organs.

Diagnosis

About half of children who see a doctor for frequent infections are normal; another 30% may have allergies, 10% have some other type of serious disorder, and 10% have a primary or secondary immunodeficiency. A diagnosis of SCID is usually made based on a complete medical history and physical examination in addition to multiple blood tests and chest x-rays. The gene in X-linked recessive SCID is called the interleukin receptor gamma chain gene or *IL2RG*. The autosomal recessive forms of SCID are caused by a variety of different genes; one of the more common is called the adenosine deaminase gene or *ADA*. Since newborns do not routinely have a test to count white blood cells, SCID is not usually suspected and the diagnosis does not happen until the child develops his or her first infection. A pattern of recurrent infections suggests an immunodeficiency.

Once a couple has had a child with SCID and they have had the genetic cause identified by DNA studies, prenatal testing for future pregnancies may be considered on a research basis for some types of SCID, although prenatal testing may not be possible if a mutation cannot be identified. Prenatal diagnosis is available via either CVS (chorionic villus sampling) or amniocentesis. CVS is a biopsy of the placenta performed in the first trimester or the first 12 weeks of pregnancy under ultrasound guidance. Ultrasound uses sound waves to visualize the locations of the developing fetus and the placenta. The genetic makeup of the placenta is identical to the fetus and, therefore, the presence or absence of one of the SCID genes can be determined from this tissue. Amniocentesis is a procedure

QUESTIONS TO ASK YOUR DOCTOR

- A relative has a child affected by SCID. Is there any way of knowing if I am at risk for this condition?
- What are the most common symptoms associated with this disorder?
- Can bone marrow transplants be rejected? What are the complications associated with transplants in SCID patients?

performed under ultrasound guidance where a long thin needle is inserted through the mother's abdomen and into the uterus to withdraw amniotic fluid surrounding the developing baby. The SCID genes can be studied using cells from the amniotic fluid. Other genetic tests, such as a chromosome analysis may also be performed on either a CVS or amniocentesis. A small risk of miscarriage is associated with amniocentesis and CVS.

Treatment and management

The best treatment for SCID is a bone marrow transplant (BMT). A bone marrow transplant involves taking cells that are normally present in bone marrow and injecting them into the SCID patient. The goal of BMT is to infuse healthy bone marrow cells into a person after his or her own unhealthy bone marrow has been eliminated. BMT helps to strengthen the immune system of a child with SCID.

Other treatment for SCID includes treating each infection promptly and accurately. Injections are also available to help boost a child's immune system.

In the year 2000, gene therapy was first reported to be successful in two French patients with SCID. The goal behind gene therapy is to replace an abnormal gene with a normal copy. In SCID, bone marrow is removed to isolate the patient's stem cells. Stem cells are special cells in the bone marrow that produce lymphocytes. In a laboratory the normal gene is added to the genome of the abnormal stem cells. The genetically altered stem cells now have the normal gene and are transplanted back into the patient. Once the functioning stem cells with the normal gene enter the bone marrow, they reproduce quickly and replace stem cells that have the abnormal gene. The patient with SCID can now produce B and T cells normally and can fight off infections without antibiotics or other treatment. The long-term effects of gene therapy

are unknown since the children treated are still very young and the research is ongoing.

Prognosis

When SCID is diagnosed early, successful bone marrow transplantation usually corrects the problem and the child lives a normal life. This means children can go to school, mix with playmates, and take part in sports. However, the quality of life for individuals with severe cases of SCID can be greatly impaired if they do not receive a bone marrow transplant. Children with SCID may not live long if they do not receive the proper treatment or if their disease goes undiagnosed.

Short-rib thoracic dysplasia with or without polydactyly

Definition

Short-rib thoracic dysplasia (SRTD) with or without polydactyly is a group of skeletal ciliopathies consisting of short ribs, short limbs, extra fingers or toes, and various internal organ abnormalities present at birth.

Description

In 1972, R. M. Saldino and C. D. Noonan first described two siblings with a dwarfism syndrome and symptoms of extremely shortened limbs, short ribs, small chest, abnormal bone formation, extra fingers, and internal organ damage. Since then, 15 additional SRTD subtypes have been identified. While each subtype has distinguishing features, there is a great amount of overlap between them.

The SRTD syndromes also include dwarfism syndromes such as asphyxiating thoracic dysplasia (Jeune syndrome) and Ellis-van Creveld syndrome. These syndromes, like the SRP types, have shortened limbs and ribs, small chest, and extra fingers or toes. As of 2015, the genetic causes for 14 types of SRTD had been identified, with multiple genetic mutations occurring in several forms. The cause of these syndromes is related to the abnormal function of cilia. Because cilia are integral to the structure of most cells, mutations in the genes responsible for the structure and function of cilia result in skeletal dysplasias or shortened bones in the arms, legs, and ribcage. The ribcage is also

Short-rib polydactyly syndrome: pedigree analysis chart
(Gale)

constricting, leaving very little room for lung growth. Development can also be abnormal in the internal organs, including the heart, kidneys, liver, and pancreas. The cause of death for newborns with this disorder is usually inability to breathe due to severely underdeveloped lungs.

Genetic profile

All types of SRTD with or without polydactyly are inherited in an autosomal recessive manner. An autosomal recessive condition is caused by two mutations in a gene responsible for SRTD. An affected individual will inherit one mutation for this condition from each parent. When both parents are carriers for mutations that cause SRTD with or without polydactyly, there is a 25% chance they will have an affected child. The parent who carries the gene mutation for this condition is not affected with symptoms of the syndrome.

Demographics

It is believed that SRTD with or without polydactyly occurs in 1 in 100,000 to 1 in 130,000 live births. Due to the rarity of the SRP syndromes, an exact incidence is unknown.

Signs and symptoms

There is much overlap of symptoms between the SRTD subtypes, and it is often difficult to distinguish between them. All present with extremely shortened bones of the arms, legs, and ribs. They all also include a small, constricted chest.

Saldino-Noonan (type I) is considered the most severe type. Features reported with this type include spur formation on the bones, abnormal vertebrae (bones of the spinal column), and decreased ossification (hardening of the bones). Heart defects are common. Cysts are often seen on the kidneys and pancreas. Extra fingers and/or toes (polydactyly) are a classic feature and are usually on the same side of the hand/foot as the “pinkie” finger/little toe (postaxial). Sex reversal has also been reported. This means that the baby is genetically male but has visible female genitalia.

Majewski (type II) also has cystic kidneys and post-axial polydactyly. This type can also have preaxial polydactyly, in which the extra fingers/toes are on the same side of the hand/foot as the thumb/big toe. Other distinguishing features include cleft lip and palate and liver damage. The tibia (one of the bones of the lower leg) is often oval shaped and shorter than the fibula (the other bone of the lower leg). The ends of the bones may also appear smooth on an x-ray.

KEY TERMS

Ciliopathies—Genetic disorders caused by a mutation in genes responsible for making proteins that maintain the integrity and role of cilia.

Dwarfism—Any condition that results in extremely shortened limbs.

Skeletal dysplasia—A group of syndromes consisting of abnormal prenatal bone development and growth.

Verma-Naumoff (type III) has much overlap with Saldino-Noonan (type I) and may be a milder variant. Internal organ involvement is less common. The ends of the bones may appear jagged and widened on an x-ray. The vertebrae are often small and flat. Polydactyly is also common in this type. Visible genitalia may be ambiguous (not clearly male or female).

Beemer-Langer (type IV), like Majewski, can have cleft lip and palate and liver damage. Cysts on the kidneys and pancreas are common. Polydactyly is usually absent but has been reported. A distinguishing feature of this type is bowed or curved bones.

Diagnosis

Diagnosis of the SRTD syndromes can be difficult. A careful examination of internal organs and x-ray evaluation is needed to distinguish SRTD syndromes from Jeune syndrome and Ellis-van Creveld syndrome. When SRTD syndrome is suspected, x-rays and internal organ involvement can also help to determine the particular type.

The main features of SRTD syndromes (short bones, short ribs, small chest) can be seen on prenatal ultrasound. Genetic testing is available for many of the different types of SRTD syndromes.

Treatment and management

There is no treatment or cure for the SRTD syndromes. The abnormal prenatal bone development is irreversible. The chest is usually too small to allow for lung growth after birth. Internal organs with cysts may not be functional.

Infants born with SRTD syndromes are given minimum care for warmth and comfort. Due to the poor prognosis, extreme measures to prolong life are rarely taken.

QUESTIONS TO ASK YOUR DOCTOR

- Is genetic testing available for short-rib thoracic dysplasia with or without polydactyly syndrome?
- Can SRTD with or without polydactyly be diagnosed prenatally and, if so, what are the risks and benefits from having such a test?
- Are there treatments available that will extend the life of an infant born with short-rib thoracic dysplasia with or without polydactyly?
- Where can I read more about this genetic disorder?

Prognosis

The prognosis for infants born with SRTD syndromes is quite poor. These babies usually die within hours or days of birth due to underdeveloped lungs. Some babies who survive infancy develop liver disease and renal failure.

Shprintzen-Goldberg craniosynostosis syndrome

Definition

Shprintzen-Goldberg craniosynostosis syndrome (SGS) is a disorder of the connective tissue, featuring craniosynostosis and marfanoid body type with an alteration in intellectual function.

Description

SGS, also known as marfanoid craniosynostosis syndrome, is one of a group of disorders characterized by craniosynostosis and marfanoid body type. It is a condition that involves craniofacial, skeletal, and other abnormalities. SGS is caused by genetic mutations (changes affecting the structure and function of the gene) in a gene that contributes to the formation of connective tissue.

Connective tissue plays a major role in the structure of the body. Its major function is to support, connect, suspend, and separate tissues and organs in the body. It is the foundation of blood cells, immune cells, lymphatic tissue, fat cells, cartilage, and bone. If connective tissue is not formed correctly, as seen in SGS, the structure and the function of the body will be disrupted.

Clinical features of SGS are widespread; however, skeletal changes are often the hallmark sign. Marfanoid characteristics include elongated features due to hyperlordism, scoliosis, pectus excavatum, and pes planus. Other skeletal characteristics include camptodactyly (bent fingers) and a hypoplastic mandible and maxilla. The clinical features that distinguish SGS from Marfan syndrome, which is an inherited genetic disorder of the connective tissue that involves the eye, heart, aorta, and skeletal system, are craniosynostosis and intellectual disability. Due to the fact that connective tissue is found throughout the body, the structural integrity of tissues and organs is also compromised, as seen in clinical symptoms such as mitral valve prolapse, aortic aneurysm, hernias, decreased fat cells that function as cushions between organs, translucent skin, and an overall appearance of being "stretched out."

Genetic profile

SGS is associated with abnormalities of the elastic fibers of connective tissue. Elastic fibers are complex in structure and are composed of at least 19 different proteins. Mutations in three of the genes that encode the majority of these 19 proteins cause abnormalities in several body systems, including the skeletal system, blood vessels, and eye.

SGS shares characteristics with Marfan syndrome, which is caused by mutations in the fibrillin-1 (*FBNI*) gene that is located on chromosome 15. Since SGS is similar in many ways to Marfan syndrome, studies of the *FBNI* gene have been conducted on SGS patients to see if they also had mutations in this gene. There were indeed abnormalities found in the *FBNI* genes of persons with SGS. Researchers think that these mutations predispose a person to develop SGS but that other factors are required in addition to the mutation in the gene to develop the disease.

Studies have determined that SGS is not primarily due to an *FBNI* gene abnormality, separating it even more from Marfan syndrome. Instead, a mutation in the *SKI* gene on the short arm of chromosome 1 is the underlying cause of SGS. One study determined that a frameshift mutation in exon 1 of the *SKI* gene causes SGS due to its role in mediating TGF-beta. TGF-beta is a cytokine growth factor that controls the proliferation and differentiation of most cells in the body and has a high link to Marfan syndrome and other connective tissue disorders with an alteration in TGF-beta activity. Another study also concluded that an alteration of *SKI* may be the underlying cause of SGS but also suggested that both *SKI* and *FBNI* mutations may cause a Marfan-like syndrome with craniosynostosis and intellectual dysfunction as seen in SGS.

The mutations appear to be sporadic in nature (not inherited) and autosomal dominant (only one mutation is necessary for a person to be predisposed to the disease). Sporadic genetic mutations in the sperm occur (in any gene, not just *FBNI*) at a higher rate in older men (over 45 years), and there is in fact one case report of a child with SGS in which the father was 49 years old. The father of another child with SGS reportedly had chemotherapy and radiation treatment prior to conception of the child. The recurrence risk for siblings is probably low, although such data are not available.

Demographics

There were approximately 29 reported cases as of 2013, with the first case being described in 1981. The ratio of females to males is 10:5, making females affected twice as often as males. Ethnicities would be expected to be affected equally with sporadic mutations, although

KEY TERMS

Aortic root—The location where the aorta (main heart blood vessel) inserts in the heart. Enlargement of the aortic root can cause it to rupture.

Camptodactyly—A condition characterized by the bending of one or more fingers.

Craniosynostosis—Premature, delayed, or otherwise abnormal closure of the sutures of the skull.

Marfanoid—Term for a body type that is similar to that of people with Marfan syndrome. Characterized by tall, lean body with long arms and long fingers.

Pectus excavatum—An abnormality of the chest in which the sternum (breastbone) sinks inward; sometimes called “funnel chest.”

Pes planus—Flat feet.

data regarding SGS specifically is limited. There is difficulty determining current demographics due to the overlapping symptoms between SGS and Marfan syndrome.

Signs and symptoms

Findings in SGS include skeletal abnormalities, hydrocephalus, and intellectual disability. Most babies born with SGS are well nourished and have a relatively long birth length. The most frequently described craniofacial features of SGS include abnormal head shape (dolichocephaly), a high, prominent forehead, bulging eyes (ocular proptosis), widely spaced eyes (hypertelorism), downslanting eyes, strabismus (wandering eye), small jaw (maxillary hypoplasia), high narrow palate (roof of the mouth), and low-set ears.

The main skeletal findings in persons with SGS include long, thin fingers (arachnodactyly, or spider-like fingers), flat feet (pes planus), “bird” chest deformity (pectus deformity), scoliosis (curvature of the spine), and joint hypermobility (loose joints).

Other features can include clubfoot, enlarged aortic root, mitral valve prolapse (a floppy heart valve that allows flow of blood back into the chamber of the heart that it came from), low muscle tone (hypotonia), developmental delay, intellectual disability, very little body fat, and a small penis in males. Myopia (nearsightedness) and abdominal wall defects (a developmental problem that occurs during formation of the fetus in which parts of the intestine or other organs can protrude outside of the body; it is usually surgically correctable) can also occur.

Radiologic findings include hydrocephalus (water on the brain), certain brain malformations (Chiari-I malformation or dilatation of the lateral ventricles), abnormalities in the first and second cervical vertebrae (vertebrae in the neck), square-shaped vertebrae, thin ribs, thinning of the bones, and craniofacial abnormalities.

Diagnosis

There are more than 75 syndromes associated with craniosynostosis. There are also a number of different syndromes associated with both craniosynostosis and marfanoid body type. X-ray evaluation can be helpful in determining whether a person has SGS, as they tend to have abnormal first and second cervical vertebrae, hydrocephalus (water on the brain), and certain brain abnormalities.

SGS must be differentiated from other syndromes with craniosynostosis and marfanoid body type. Two such syndromes include Idaho syndrome II and Antley-Bixler syndrome. Idaho syndrome II has less severe craniofacial problems than SGS and has abnormal leg bones and absent patellae (knee caps). Antley-Bixler syndrome is an inherited syndrome with craniofacial abnormalities, abnormal arm and leg bones, and fractures in the femurs (thigh bones). These characteristics are different from SGS. A clinical geneticist is a physician who has special training in recognizing and diagnosing rare genetic conditions and is a good resource for differentiating among these complicated and similar conditions.

A true diagnosis can be made via genetic testing. This will help differentiate SGS from other connective tissue disorders such as Marfan syndrome and Loeys-Dietz syndrome. Genetic testing may be done in laboratories utilizing deletion/duplication analysis with PCR and Sanger Sequence Analysis.

Treatment and management

Cardiology evaluation is important since several children have been reported to have severe cardiac disease with SGS. Aortic root must be evaluated and measured routinely to minimize the risk for rupture. Enlarged aortic roots may need to be surgically repaired.

Patients should have an ophthalmologic evaluation, since mutations in the *FBR1* gene are associated with abnormalities in the eyes.

Surgical correction of craniofacial problems or pectus are sometimes necessary or desirable. Shunting (surgical placement of a shunt to drain the accumulated fluid in the brain to the abdominal cavity to relieve pressure) may be required for patients with hydrocephalus. Orthopedic devices may be required for scoliosis or other bone deformities.

QUESTIONS TO ASK YOUR DOCTOR

- What does the term “marfanoid body type” mean?
- How is Shprintzen-Goldberg craniosynostosis syndrome diagnosed, and at what age can a reliable diagnosis be made?
- What kinds of treatments are recommended for the medical problems related to Shprintzen-Goldberg craniosynostosis syndrome?
- What is the prognosis for a child diagnosed with this genetic disorder?
- How often should cardiovascular function and integrity be assessed?

Special education for intellectually disabled individuals or individuals with developmental delay is recommended.

Genetic counseling is recommended for persons with relatives diagnosed with SGS.

Prognosis

SGS does not alter lifespan, although complications from associated abnormalities such as intellectual disability or respiratory problems can cause problems.

Sialidosis

Definition

Sialidosis, previously known as neuraminidase deficiency, is a rare inherited metabolic disorder with multiple symptoms that can include skeletal abnormalities and progressive neurological degeneration.

Description

Nomenclature

Neuraminidase deficiency is caused by a mutation, or change, in the *NEU1* gene that codes for the lysosomal enzyme alpha-N-acetyl-neuraminidase, or neuraminidase for short. This enzyme sometimes is referred to as sialidase. It is also sometimes called N-acetyl-neuraminic acid hydrolase. The disorder is manifested in one of two forms, known as sialidosis types I and II. Sialidosis type I is the milder form of the disorder, with symptoms typically appearing during adolescence. It is known as the nondysmorphic or normophormic form of sialidosis. Sialidosis type II is the more severe form of neuraminidase deficiency, with symptoms developing in the fetus, at birth, or during infancy or early childhood. It is known as the dysmorphic form of sialidosis.

Over the years, this disorder has been called by a number of different names, in addition to neuraminidase deficiency, alpha-neuraminidase deficiency, sialidase deficiency, and sialidosis. It sometimes is known as cherry-red spot and myoclonus syndrome, cherry-red spot myoclonus epilepsy syndrome, or myoclonus and cherry-red spot syndrome, in reference to characteristic symptoms of the disorder. Other names include glycoprotein neuraminidase deficiency, *NEUG* deficiency, *NEU* or *NEU1* deficiency, and neuraminidase 1 deficiency. Sialidosis type I sometimes is referred to as juvenile sialidosis and type II as infantile sialidosis, in reference to the age of onset.

Lysosomal storage diseases

Lysosomes are membrane-bound spherical compartments or vesicles within the cytosol, the semi-fluid areas of cells. Lysosomes contain more than 50 different enzymes that are responsible for digesting, or hydrolyzing, large molecules and cellular components. These include proteins; polysaccharides, which are long, linear, or branched chains of sugars; and lipids, which are large insoluble biomolecules that are usually built from fatty acids. The smaller breakdown products from the lysosomes are recycled to the cytosol.

Neuraminidase deficiency is one of at least 41 genetically distinct lysosomal storage diseases. These disorders result from mutations in the genes encoding the hydrolytic enzymes of the lysosome. In these disorders, some of the macromolecules in the lysosomes cannot be degraded and they, or their partial-breakdown products, accumulate there. The lysosomes swell to the point where cellular function is disrupted.

Neuraminidase deficiency, particularly sialidosis type II, commonly has been classified as the lysosomal storage disease called mucopolysaccharidosis type I (ML I), formerly lipomucopolysaccharidosis. This is because the symptoms of neuraminidase deficiency are similar to various mucopolysaccharidosis disorders. However, mucopolysaccharidoses are characterized by the accumulation of large and complex lipid-polysaccharides. In contrast, neuraminidase deficiency leads to the accumulation of specific types of short chains of sugar called oligosaccharides and of certain proteins with oligosaccharides attached to them, called glycoproteins. Thus, it may be more appropriate to classify neuraminidase deficiency as an oligosaccharide storage disease, since it leads to the accumulation of excess oligosaccharides in various tissues throughout the body and the excretion of oligosaccharides.

Neuraminidase

Neuraminidase, or sialidase, is a type of enzyme known as an exoglycosidase because it cleaves terminal sugar units, or residues, off oligosaccharides. Specifically, neuraminidase cleaves, or hydrolyzes, terminal sialic acid residues. Sialic acid, also known as N-acetylneuraminic acid, is a type of sugar molecule that often is at an end of an oligosaccharide. The oligosaccharides with sialic acid residues may be attached to proteins (glycoproteins). Therefore, neuraminidase deficiency prevents the proper breakdown of oligosaccharides and glycoproteins that contain sialic acid, and the disorder is characterized by the accumulation and excretion of these substances.

In addition to interfering with the lysosomal breakdown of sialic acid compounds, neuraminidase deficiency can lead to abnormal proteins. Following protein

synthesis, some lysosomal enzymes reach the lysosome in an inactive form and require further processing for activation. One such processing step is the neuraminidase-catalyzed removal of sialic acid residues from oligosaccharides on the enzymes. Lysosomal hydrolases that require further processing by neuraminidase include acid phosphatase, alpha-mannosidase, arylsulfatase B, and alpha-glucosidase.

Under conditions of neuraminidase deficiency, sialyloligosaccharides accumulate in various cells, including lymphocytes (white blood cells that produce antibodies), fibroblasts (connective tissue cells), bone marrow cells, Kupffer cells of the liver, and Schwann cells, which form the myelin sheaths of nerve fibers. Furthermore, proteins with sialic acid attachments accumulate and can be detected in fibroblasts and in the urine.

Neuraminidase exists in the lysosome in a high-molecular-weight complex with three other proteins: the enzyme beta-galactosidase, the enzyme N-acetylgalactosamine-6-sulfate sulfatase (GALNS), and a multi-functional enzyme called protective protein/cathepsin A (PPCA). Neuraminidase must be associated with PPCA in order for the neuraminidase to reach the lysosome. Once inside the lysosome, PPCA mediates the association of as many as 24 neuraminidase molecules to form active neuraminidase. The active enzyme remains associated with PPCA and beta-galactosidase, which appear to be necessary for protecting and stabilizing the neuraminidase activity. A distinct lysosomal storage disease, neuraminidase deficiency with beta-galactosidase deficiency, or galactosialidosis, results from mutations in the gene encoding PPCA. In this disorder, both neuraminidase and beta-galactosidase are deficient.

Genetic profile

Inheritance of sialidosis

Sialidosis is an autosomal recessive disorder that can be caused by any one of a number of different mutations in the *NEU1* gene encoding the lysosomal neuraminidase. The disorder is autosomal because the *NEU1* gene is located on chromosome 6, rather than on the X or Y sex chromosomes. The disorder is recessive because it only develops when both genes encoding neuraminidase, one inherited from each parent, are defective; however, the two defective *NEU1* genes do not need to carry the same mutations. If the two mutations are identical, the individual is a homozygote. If the two mutations are different, the affected individual is called a compound heterozygote. Individuals with one defective gene and one normal gene encoding neuraminidase may have reduced levels of the active enzyme, but they do not have symptoms of neuraminidase deficiency.

All of the offspring of two parents with neuraminidase deficiency will inherit the disorder. All of the offspring of one parent with neuraminidase deficiency and one parent with a single defective *NEU1* gene will inherit at least one defective *NEU1* gene. They will have a 50% chance of inheriting two defective genes and, therefore, developing neuraminidase deficiency. The offspring of one parent with neuraminidase deficiency and one parent with normal *NEU1* genes will inherit a defective gene from the affected parent but will not develop neuraminidase deficiency. The offspring of parents who both carry one defective *NEU1* gene have a 50% chance of inheriting one defective *NEU1* gene and a 25% chance of inheriting two genes and developing neuraminidase deficiency. Finally, the children of one parent with a single defective *NEU1* gene and one parent with normal *NEU1* genes will have a 50% chance of inheriting the defective gene but will not develop neuraminidase deficiency.

Mutations in the NEU1 gene, type I sialidosis and type II sialidosis

Roughly 50 different mutations that can cause sialidosis have been identified in the *NEU1* gene. The type of neuraminidase deficiency, sialidoses types I or II, as well as the severity of the symptoms, depends on the specific mutation(s) that are present. Some mutations change one amino acid out of the 415 amino acids that compose a single neuraminidase molecule. Other identified mutations result in a shortened enzyme. Many of the identified mutations are clustered in one region on the surface of the protein. These mutations result in a sharp reduction in the activity of the enzyme and lead to the rapid degradation of neuraminidase inside the lysosome.

Some mutations in the *NEU1* gene lead to a complete absence of neuraminidase activity, with little or no neuraminidase enzyme present in the lysosomes. These mutations usually result in the severe, infantile-onset type II sialidosis. Other mutations result in an inactive protein that is present in the lysosome. These mutations generally result in juvenile-onset type II sialidosis, with symptoms of intermediate severity. Some mutations significantly reduce, but do not obliterate, neuraminidase activity in the lysosome. Individuals with at least one mutated gene of this type are not completely neuraminidase-deficient and have mild type I sialidosis. Occasionally, individuals have multiple mutations in the *NEU1* gene, leading to more severe forms of neuraminidase deficiency.

Demographics

Sialidosis is an extremely rare disorder. Because of its similarities to many other disorders, it has been difficult to determine its frequency. In the United States, it is

estimated to occur in 1 out of every 250,000 live births. In Australia, the estimate is 1 out of 4.2 million. Since sialidosis is an autosomal rather than a sex-linked disorder, it occurs equally in males and females.

As an autosomal recessive disorder, sialidosis requires two copies of the defective gene, one inherited from each parent. Thus, it is much more common in the offspring of couples who are related to each other (consanguineous marriages), such as first or second cousins.

Sialidosis type I appears to be more common among Italians. Type 2 sialidosis seems to occur more frequently among Japanese.

Signs and symptoms

The clinical symptoms of neuraminidase deficiency are similar to the symptoms of the mucopolidoses, including I-cell disease (mucopolidosis II) and pseudo-Hurler polydystrophy (mucopolidosis III). Furthermore, the clinical distinctions between sialidoses types I and II may not be clearly defined.

Sialidosis type I

The symptoms of sialidosis type I do not appear until the second decade of life. Infants and children with this form of sialidosis may have a normal appearance and grow normally until adolescence. At that time, the appearance of red spots in both eyes, known as cherry-red macules or cherry-red macular spots, may be one of the first symptoms of neuraminidase deficiency. Eventually, color and/or night blindness may develop. Cataracts may occur, and vision may deteriorate gradually into blindness. Atrophy of the brain may also occur.

Other symptoms of sialidosis type I include myoclonus. These are sudden involuntary muscle contractions that may eventually develop into myoclonic seizures. The myoclonus may become debilitating, even in sialidosis type I. Individuals with this form of sialidosis may have increased deep tendon reflexes (hyperreflexia) and may develop tremors and various other neurological conditions. There may be a progressive loss of muscle coordination, called ataxia, and walking and standing may become increasingly difficult. Speech problems, such as slurring, may develop.

These symptoms also may occur in sialidosis type II. However, in addition to the age of onset, type I can be distinguished from type II by the absence of skeletal and facial abnormalities. Furthermore, individuals with this form of neuraminidase deficiency have normal intelligence.

KEY TERMS

Dysostosis multiplex—A variety of bone and skeletal malformations.

Fibroblast—Cells that form connective tissue fibers like skin.

Glycoprotein—A protein with at least one carbohydrate group.

Heterozygote—Having two different versions of the same gene.

Homozygote—Having two identical copies of a gene or chromosome.

Lipid—Large, complex biomolecule, such as a fatty acid, that will not dissolve in water. A major constituent of membranes.

Lysosome—Membrane-enclosed compartment in cells, containing many hydrolytic enzymes; where large molecules and cellular components are broken down.

Myoclonus—Twitching or spasms of a muscle or an interrelated group of muscles.

Oligosaccharide—Several monosaccharide (sugar) groups joined by glycosidic bonds.

Polysaccharide—Linear or branched macromolecule composed of numerous monosaccharide (sugar) units linked by glycosidic bonds.

Recessive—Genetic trait expressed only when present on both members of a pair of chromosomes, one inherited from each parent.

Sialic acid—N-acetylneuraminic acid, a sugar that is often at the end of an oligosaccharide on a glycoprotein.

Vacuolation—The formation of multiple vesicles, or vacuoles, within the cytosol of cells.

Sialidosis type II

Sialidosis type II has three forms: congenital or neonatal, with symptoms present at or before birth; infantile, with symptoms developing at birth or during the first year of life; and juvenile, with symptoms developing between the ages of 2 and 20.

Symptoms of sialidosis type II vary from mild to severe but are always more severe than in type I sialidosis. With neonatal onset, infants may be born with ascites (accumulation of fluid in the abdominal cavity), swollen liver and spleen (hepatosplenomegaly), hernia of the umbilicus or the groin, and other abnormalities. With

severe forms of the disorder, children may die in infancy. With milder forms, they may show no symptoms for the first 10 years of life. Thus, ascites, hepatosplenomegaly, and hernias may develop later. Children with sialidosis may grow abnormally fast. Cherry-red macules, myoclonus, and other neurological abnormalities, including tremors, may be present. The myoclonus may progress into a form of epilepsy. These children may have mild to severe intellectual disability.

Sialidosis type II is characterized by a variety of skeletal malformations (dysostosis multiplex). Obvious symptoms may include distinctive, coarse facial features (called coarse facies), a short trunk with relatively long legs and arms, and a prominent breast bone (pectus carinatum). In addition, there may be a lack of muscle tone and strength (hypotonia) and the progressive wasting of muscular tissue.

Hearing may be affected in sialidosis type II. Individuals may have difficulty breathing (dyspnea). Cardiac problems may develop, and severe congenital sialidosis type II apparently can result in severely dilated coronary arteries. Loose bowel movements are common with this form of neuraminidase deficiency.

Diagnosis

Neuraminidase activity

Typically, sialidosis is diagnosed by measuring the activity of the enzyme in cultures of fibroblast cells that have been grown from cells obtained via a skin biopsy. Lysosomal neuraminidase also can be measured in leukocytes (white blood cells). However, human cells have two other types of neuraminidase, encoded by different genes. One of these enzymes is present in the cell membrane, and the other is in the cytosol of various cells, including leukocytes. These enzymes are not deficient in sialidosis, and their activities can interfere with the measurement of lysosomal neuraminidase.

Neuraminidase activity usually is measured by testing the ability of fibroblast cell preparations to hydrolyze, or cleave, a synthetic compound such as 4-methylumbelliferyl-D-N-acetylneuraminic acid. Hydrolysis by neuraminidase liberates 4-methylumbelliferone, which is a compound with a fluorescence that can be measured accurately. Neuraminidase is an unstable enzyme, and special precautions are needed to test for its activity. The normal range of neuraminidase activity in fibroblasts is 95–653 picomoles per minute per milligram of protein. In leukocytes, the normal range is 6–60 picomoles per minute per milligram of protein. Levels of active neuraminidase are much lower in sialidosis type II as compared to type I.

QUESTIONS TO ASK YOUR DOCTOR

- What type of sialidosis do I have?
- What is my prognosis?
- How often should I be screened for progression of my disorder?
- Are there support groups for me and my family?
- How accurate is the genetic testing for me to screen any future children I may have?

Urine tests

Sialidosis may be diagnosed by screening the urine for the presence of sialyloligosaccharides using chromatography to separate the components of the urine on the basis of size and charge. In unaffected individuals, sialyloligosaccharides are cleaved by neuraminidase and, therefore, are present in the urine in only very low amounts. With sialidosis, urine levels of sialyloligosaccharides may be three to five times higher than normal. Sialyloligosaccharides or partially degraded proteins with sialyloligosaccharides still attached, also can be detected in the urine under conditions of sialidosis. A study published in 2014 proposed the use of mass spectrometry for the diagnosis of sialidosis and other lysosomal diseases for urinary screening of oligosaccharides.

Histology

Sialidosis and other lysosomal storage diseases interfere with the normal lysosomal breakdown of cellular components. As a result, the lysosomes may fill up with large molecules that are only partially digested. In the case of sialidosis, the lysosomes fill up with sialyloligosaccharides and sialylglycopeptides. These swollen lysosomes may form inclusion bodies and give cells a vacuolated appearance that is diagnostic of lysosomal storage disease. Sialidosis may be diagnosed by histological, or microscopic, examination of a number of different types of cells that may show this cytosolic vacuolation. These cells include the Kupffer cells of the liver, lymphocytes, bone marrow cells, epithelial skin cells, and fibroblasts.

Sialidosis type II

Infants with sialidosis type II often have visual symptoms of the disorder at birth, including facial and skeletal abnormalities. Skeletal x-rays may be used to diagnose the dysostosis multiplex of this type of sialidosis.

Magnetic resonance imaging (MRI) may be used to determine brain atrophy.

Prenatal diagnosis

Sialidosis may be diagnosed prenatally. In at-risk fetuses, cultured fetal cells from the amniotic fluid, obtained by amniocentesis, or cultured chorionic villus cells, obtained by chorionic villus sampling in the early weeks of pregnancy, may be tested for neuraminidase activity. Since carriers of a single mutated *NEU1* gene do not have symptoms of neuraminidase deficiency, it may be difficult to recognize an at-risk fetus unless there is a family history of the disorder.

Treatment and management

At present, there is no treatment for sialidosis. Rather, attempts are made to manage individual symptoms. Myoclonic seizures in particular are very difficult to control. A study published in 2013, however, did report that some mutations associated with sialidosis type I may respond well to gene therapy specific to structure and function of lysosomes. This study was performed on mice models, indicative of the need for more research on this topic.

Prognosis

Individuals with sialidosis type I may have a near-normal life expectancy. However, the myoclonus may be progressively debilitating, and myoclonic seizures can be fatal. Children with neonatal-onset sialidosis type II usually are stillborn or die at a young age. Those with infantile-onset sialidosis type II rarely survive through adolescence.

Sickle cell disease

Definition

Sickle cell disease describes a group of inherited blood disorders characterized by chronic anemia, painful events, and various complications due to associated tissue and organ damage.

Description

The most common and well-known type of sickle cell disease is sickle cell anemia, also called SS disease. All types of sickle cell disease are caused by a genetic change in hemoglobin, the oxygen-carrying protein inside the red blood cells. The red blood cells of affected individuals contain a predominance of a structural variant of the usual adult hemoglobin. This variant hemoglobin, called sickle hemoglobin, has a tendency to develop into rod-like structures that alter the shape of the usually flexible red blood cells. The cells take on a shape that resembles the curved blade of a sickle, an agricultural tool. Sickle cells have a shorter lifespan than normally shaped red blood cells. This results in chronic anemia characterized by low levels of hemoglobin and decreased numbers of red blood cells. Sickle cells are also less flexible and more sticky than normal red blood cells, and can become trapped in small blood vessels, preventing blood flow. This compromises the delivery of oxygen, which can result in pain and damage to associated tissues and organs. Sickle cell disease presents with marked variability, even within families.

Demographics

Carriers of the sickle cell gene are said to have sickle cell trait. Unlike sickle cell disease, sickle cell trait does

not cause health problems. In fact, sickle cell trait is protective against malaria, a disease caused by blood-borne parasites transmitted through mosquito bites. According to a widely accepted theory, the genetic mutation associated with the sickle cell trait occurred thousands of years ago. Coincidentally, this mutation increased the likelihood that carriers would survive malaria infection. Survivors then passed the mutation on to their offspring, and the trait became established throughout areas where malaria was common. As populations migrated, so did the sickle cell trait. Today, approximately 1 in 12 African Americans has sickle cell trait.

It has been estimated that in the United States, 70,000 to 80,000 people have sickle cell disease. Sickle cell disease primarily affects people of African, Mediterranean, Middle Eastern, and eastern Indian ancestry. In the United States, sickle cell disease is most often seen in African Americans, in whom the disease occurs in 1 out of every 500 births. The disease has been described in individuals from several different ethnic backgrounds and is also seen with increased frequency in Latino Americans—particularly those of Caribbean, Central American, and South American ancestry. Approximately 1 in every 1,000–1,400 Latino births is affected.

Genetic profile

Humans normally make several types of the oxygen-carrying protein hemoglobin. An individual's stage in development determines whether he or she makes primarily embryonic, fetal, or adult hemoglobins. All types of hemoglobin are made of three components: heme, alpha (or alpha-like) globin, and beta (or beta-like) globin. Sickle hemoglobin is the result of a genetic change in the beta globin component of normal adult hemoglobin. The beta globin gene is located on chromosome 11. The sickle cell form of the beta globin gene results from the substitution of a single DNA nucleotide, or genetic building block. The change from adenine to thymine at codon (position) 6 of the beta globin gene leads to insertion of the amino acid valine—instead of glutamic acid—at this same position in the beta globin protein. As a result of this change, sickle hemoglobin has unique properties in comparison to the usual type of adult hemoglobin.

Most individuals have two normal copies of the beta globin gene, which make normal beta globin that is incorporated into adult hemoglobin. Individuals who have sickle cell trait (called sickle cell carriers) have one normal beta globin gene and one sickle cell gene. These individuals make both the usual adult hemoglobin and sickle hemoglobin in roughly equal proportions, so they do not experience any health problems as a result of having the trait. Although traces of blood in the urine and difficulty

The lower leg of this man has ulcerated tissue due to sickle cell anemia. (Sue Ford/Science Source)

in concentrating the urine can occur, neither represents a significant health problem as a result of sickle cell trait. Of the millions of people with sickle cell trait worldwide, a small handful of individuals have experienced acute symptoms. In these very rare cases, individuals were subject to very severe physical strain.

When both members of a couple are carriers of sickle cell trait, there is a 25% chance in each pregnancy for the baby to inherit two sickle cell genes and have sickle cell anemia, or SS disease. Correspondingly, there is a 50% chance the baby will have sickle cell trait and a 25% chance that the baby will have the usual type of hemoglobin.

Other types of sickle cell disease include SC disease, SD disease, and S/beta thalassemia. These conditions are caused by the co-inheritance of the sickle cell gene and another altered beta globin gene. For example, one parent may have sickle cell trait and the other parent may have hemoglobin C trait (another hemoglobin trait that does not cause health problems). For this couple, there would be a 25% chance of SC disease in each pregnancy.

Signs and symptoms

Normal adult hemoglobin transports oxygen from the lungs to tissues throughout the body. Sickle hemoglobin can also transport oxygen. However, once the oxygen is released, sickle hemoglobin tends to polymerize (line up) into rigid rods that alter the shape of the red blood cell. Sickling of the red blood cell can be triggered by low oxygen, such as occurs in organs with slow blood flow. It can also be triggered by cold temperatures and dehydration.

Sickle cells have a decreased lifespan in comparison to normal red blood cells. Normal red blood cells survive for approximately 120 days in the bloodstream; sickle cells last only 10–12 days. As a result, the bloodstream is chronically short of red blood cells and hemoglobin, and the affected individual develops anemia.

Sickle cells can create other complications. Due to their shape, they do not fit well through small blood vessels. As an aggravating factor, the outside surfaces of sickle cells may have altered chemical properties that increase the cells' "stickiness." These sticky sickle cells are more likely to adhere to the inside surfaces of small blood vessels, as well as to other blood cells. As a result of the sickle cells' shape and stickiness, blockages form in small blood vessels. Such blockages prevent oxygenated blood from reaching areas where it is needed, causing pain as well as organ and tissue damage.

The severity of symptoms cannot be predicted based solely on the genetic inheritance. Some individuals with sickle cell disease develop health- or life-threatening problems in infancy, but others may have only mild symptoms throughout their lives. Individuals may experience varying degrees of health at different stages in the life cycle. For the most part, this clinical variability is unpredictable, and the reasons for the observed variability cannot usually be determined. However, certain types of sickle cell disease (i.e., SC disease) tend to result in fewer and less severe symptoms on average than other types of sickle cell disease (i.e., SS disease). Some additional modifying factors are known. For example, elevated levels of fetal hemoglobin in a child or adult can decrease the quantity and severity of some symptoms and complications. Fetal hemoglobin is a normally occurring hemoglobin that usually decreases from more than 90% of the total hemoglobin to less than 1% during the first year of life. This change is genetically determined, although some individuals may experience elevated levels of fetal hemoglobin due to variation in the genes that control fetal hemoglobin production. Such individuals often experience a reduction in their symptoms and complications due to the ability of fetal hemoglobin to prevent the

polymerization of sickle hemoglobin, which leads to sickling of the red blood cell.

There are several symptoms that warrant immediate medical attention, including the following:

- signs of infection (fever 101°F or 38.3°C, frequent cough or breathing trouble, unusual crankiness, feeding difficulties)
- signs of severe anemia (pale skin or lips, yellowing of the skin or eyes, very tired, very weak)
- signs indicating possible dehydration (vomiting, diarrhea, fewer wet diapers)
- other signs (pain or swelling in the abdomen, swollen hands or feet, screams when touched).

These can be signs of various complications that occur in sickle cell disease.

Infections and effects on the spleen

Children with sickle cell disease who are under age three are particularly prone to life-threatening bacterial infections. *Streptococcus pneumoniae* is the most common offending bacteria, and invasive infection from this organism leads to death in 15% of patients. The spleen, an organ that helps to fight bacterial infections, is particularly vulnerable to the effects of sickling. Sickle cells can impede blood flow through the spleen, causing organ damage, which usually results in loss of spleen function by late childhood. The spleen can also become enlarged due to blockages and/or increased activity of the spleen. Rapid enlargement of the spleen may be a sign of another complication called *splenic sequestration*, which occurs mostly in young children and can be life threatening. Widespread sickling in the spleen prevents adequate blood flow from the organ, removing increasing volumes

Colored scanning electron micrograph of a deformed red blood cell (left) taken from a person with sickle cell disease. (Jackie Lewin/Royal Free Hospital/Science Source)

Sickle cell anemia: pedigree analysis chart (Gale)

of blood from the circulation and leading to accompanying signs of severe anemia.

Painful events

Painful events, also known as *vaso-occlusive events*, are a hallmark symptom of sickle cell disease. The frequency and duration of the pain can vary tremendously from person to person and over an individual's life cycle. Painful events are the most common cause of hospitalizations in sickle cell disease. However, only a small portion of individuals with sickle cell disease experience frequent and severe painful events. Most painful events can be managed at home. Pain results when small blood vessel blockages prevent oxygen from reaching tissues. Pain can affect any area of the body, although the extremities, chest, abdomen, and bones are frequently affected sites. There is some evidence that cold temperatures or infection can trigger a painful event, but most events occur for unknown reasons. The hand-foot syndrome, or *dactylitis*, is a particular type of painful event. Most common in toddlers, dactylitis results in pain and swelling in the hands and feet, sometimes accompanied by a fever.

Anemia

Sickle cells have a high turnover rate leading to a deficit of red blood cells in the bloodstream. Common symptoms of anemia include fatigue, paleness, and a shortness of breath. A particularly severe form of anemia—aplastic anemia—occurs following infection with parvovirus. Parvovirus causes extensive destruction of the bone marrow, bringing production of new red blood cells to a halt. Bone marrow production resumes after seven to ten days; however, given the short lives of sickle

cells, even a brief shutdown in red blood cell production can cause a rapid decline in hemoglobin concentrations.

Delayed growth

The energy demands of the bone marrow for red blood cell production compete with the demands of a growing body. Children with sickle cell anemia may have delayed growth and reach puberty at a later age than normal. By early adulthood, they catch up on growth and attain normal height; however, weight typically remains below average.

Stroke

Children with sickle cell disease have a significantly elevated risk of having a stroke, which can be one of the most concerning complications of sickle cell disease. Approximately 11% of individuals with sickle cell disease will have a recognizable stroke by the age of 20. Magnetic resonance imaging studies have found that 17% of children with sickle cell anemia have evidence of a previous stroke or clinically “silent” stroke-like events called *transient ischemic events*. Stroke in sickle cell disease is usually caused by a blockage of a blood vessel, but about one-quarter of the time may be caused by a hemorrhage (or rupture) of a blood vessel.

Strokes result in compromised delivery of oxygen to an area of the brain. The consequences of stroke can range from life threatening, to severe physical or cognitive impairments, to apparent or subtle learning disabilities, to undetectable effects. Common stroke symptoms include weakness or numbness that affects one side of the body, sudden behavioral changes, loss of vision, confusion, loss of speech or the ability to understand spoken

KEY TERMS

Amino acid—Organic compounds that form the building blocks of protein. There are 20 types of amino acids (eight are “essential amino acids” which the body cannot make and must therefore be obtained from food).

Anemia—A blood condition in which the level of hemoglobin or the number of red blood cells falls below normal values. Common symptoms include paleness, fatigue, and shortness of breath.

Bilirubin—A yellow pigment that is the end result of hemoglobin breakdown. This pigment is metabolized in the liver and excreted from the body through the bile. Bloodstream levels are normally low; however, extensive red cell destruction leads to excessive bilirubin formation and jaundice.

Bone marrow—A spongy tissue located in the hollow centers of certain bones, such as the skull and hip bones. Bone marrow is the site of blood cell generation.

Bone marrow transplantation—A medical procedure used to treat some diseases that arise from defective blood cell formation in the bone marrow. Healthy bone marrow is extracted from a donor to replace the marrow in an ailing individual. Proteins on the surface of bone marrow cells must be identical or very closely matched between a donor and the recipient.

Globin—One of the component protein molecules found in hemoglobin. Normal adult hemoglobin has a pair each of alpha-globin and beta-globin molecules.

Heme—The iron-containing molecule in hemoglobin that serves as the site for oxygen binding.

Hemoglobin—Protein-iron compound in the blood that carries oxygen to the cells and carries carbon dioxide away from the cells.

Hemoglobin A—Normal adult hemoglobin that contains a heme molecule, two alpha-globin molecules, and two beta-globin molecules.

Hemoglobin electrophoresis—A laboratory test that separates molecules based on their size, shape, or electrical charge.

Hemoglobin S—Hemoglobin produced in association with the sickle cell trait; the beta-globin molecules of hemoglobin S are defective.

Hydroxyurea—A drug that has been shown to induce production of fetal hemoglobin. Fetal hemoglobin has a pair of gamma-globin molecules in place of the typical beta-globins of adult hemoglobin. Higher-than-normal levels of fetal hemoglobin can prevent sickling from occurring.

Impotence—The inability to have a penile erection, which can be due to tissue damage resulting from sickling within the penis (priapism).

Iron overload—A side effect of frequent blood transfusions in which the body accumulates abnormally high levels of iron. Iron deposits can form in organs, particularly the heart, and cause life-threatening damage.

Jaundice—Yellowing of the skin or eyes due to excess of bilirubin in the blood.

Magnetic resonance imaging (MRI)—A technique that employs magnetic fields and radio waves to create detailed images of internal body structures and organs, including the brain.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and can be transmitted to offspring.

Narcotics—Strong prescription medication that can be effective in treating pain, but have the potential to be habit-forming if their use is not supervised correctly.

Nucleic acid—A type of chemical used as a component for building DNA. The nucleic acids found in DNA are adenine, thymine, guanine, and cytosine.

Ophthalmology—The medical specialty of vision and the eye.

Placenta—The organ responsible for oxygen and nutrition exchange between a pregnant mother and her developing baby.

Red blood cell—Hemoglobin-containing blood cells that transport oxygen from the lungs to tissues. In the tissues, the red blood cells exchange their oxygen for carbon dioxide, which is brought back to the lungs to be exhaled.

Screening—Process through which carriers of a trait may be identified within a population.

Sickle cell—A red blood cell that has assumed an elongated shape due to the presence of hemoglobin S.

words, dizziness, headache, seizures, vomiting, or even coma.

Approximately two-thirds of the children who have a stroke will have at least one more. Transfusions have been shown to decrease the incidence of a second stroke. A recent study showed that children at highest risk to experience a first stroke were ten times more likely to stroke if untreated when compared to high-risk children treated with chronic blood transfusion therapy. High-risk children were identified using transcranial Doppler ultrasound technology to detect individuals with increased blood flow speeds due to constricted intracranial blood vessels.

Acute chest syndrome

Acute chest syndrome (ACS) is a leading cause of death for individuals with sickle cell disease, and recurrent attacks can lead to permanent lung damage. Therefore, rapid diagnosis and treatment is of great importance. ACS can occur at any age and is similar but distinct from pneumonia. Affected persons may experience fever, cough, chest pain, and shortness of breath. ACS seems to have multiple causes including infection, sickling in the small blood vessels of the lungs, fat embolisms in the lungs, or a combination of factors.

Priapism

Males with sickle cell anemia may experience priapism, a condition characterized by a persistent and painful erection of the penis. Due to blood vessel blockage by sickle cells, blood is trapped in the tissue of the penis. Priapism may be short in duration or it may be prolonged. Priapism can be triggered by low oxygen (hypoxemia), alcohol consumption, or sexual intercourse. Since priapism can be extremely painful and result in damage to this tissue causing impotence, rapid treatment is essential.

Kidney disease

The environment in the kidney is particularly prone to damage from sickle cells. Signs of kidney damage can include blood in the urine, incontinence, and enlarged kidneys. Adults with sickle cell disease often experience insufficient functioning of the kidneys, which can progress to kidney failure in a small percentage of adults with sickle cell disease.

Jaundice and gallstones

Jaundice is indicated by a yellow tone in the skin and eyes, and alone it is not a health concern. Jaundice may occur if bilirubin levels increase, which can occur with high levels of red blood cell destruction. Bilirubin is the final product of hemoglobin degradation, and is typically removed from the bloodstream by the liver. Therefore,

jaundice can also be a sign of a poorly functioning liver, which may also be evidenced by an enlarged liver. Increased bilirubin also leads to increased chance for gallstones in children with sickle cell disease. Treatment, which may include removal of the gall bladder, may be selected if the gallstones start causing symptoms.

Retinopathy

The blood vessels that supply oxygen to the retina—the tissue at the back of the eye—may be blocked by sickle cells, leading to a condition called retinopathy. This is one of the only complications that is actually more common in SC disease as compared to SS disease. Retinopathy can be identified through regular ophthalmology evaluations and effectively treated in order to avoid damage to vision.

Joint problems

Avascular necrosis of the hip and shoulder joints, in which bone damage occurs due to compromised blood flow due to sickling, can occur later in childhood. This complication can affect an individual's physical abilities and result in substantial pain.

Diagnosis

Inheritance of sickle cell disease or trait cannot be prevented, but it may be predicted. Screening is recommended for individuals in high-risk populations. In the United States, African Americans and Latino Americans have the highest risk of having the disease or trait. Sickle cell is also common among individuals of Mediterranean, Middle Eastern, and Eastern Indian descent.

A complete blood count (CBC) will describe several aspects of an individual's blood cells. A person with sickle cell disease will have a lower than normal hemoglobin level, together with other characteristic red blood cell abnormalities. A hemoglobin electrophoresis is a test that can help identify the types and quantities of hemoglobin made by an individual. This test uses an electric field applied across a slab of gel-like material. Hemoglobins migrate through this gel at various rates and to specific locations, depending on their size, shape, and electrical charge. Although sickle hemoglobin (Hb S) and regular adult hemoglobin (called Hb A) differ by only one amino acid, they can be clearly separated using hemoglobin electrophoresis. Isoelectric focusing and high-performance liquid chromatography (HPLC) use similar principles to separate hemoglobins and can be used instead of or in various combinations with hemoglobin electrophoresis to determine the types of hemoglobin present.

Another test, called the sickledex, can help confirm the presence of sickle hemoglobin, although this test

cannot provide accurate or reliable diagnosis when used alone. When Hb S is present, but there is an absence or only a trace of Hb A, sickle cell anemia is a likely diagnosis. Additional beta globin DNA testing, which looks directly at the beta globin gene, can be performed to help confirm the diagnosis and establish the exact genetic type of sickle cell disease. CBC and hemoglobin electrophoresis are also typically used to diagnose sickle cell trait and various other types of beta globin traits.

Diagnosis of sickle cell disease can occur under various circumstances. If an individual has symptoms that are suggestive of this diagnosis, the above-described screening tests can be performed followed by DNA testing, if indicated. Screening at birth using HPLC or a related technique offers the opportunity for early intervention. More than 40 states include sickle cell screening as part of the usual battery of blood tests done for newborns. This allows for early identification and treatment. Hemoglobin trait screening is recommended for any individual of a high-risk ethnic background who may be considering having children. When both members of a couple are found to have sickle cell trait, or other related hemoglobin traits, they can receive genetic counseling regarding the risk of sickle cell disease in their future children and various testing options.

Sickle cell disease can be identified before birth through the use of prenatal diagnosis. Chorionic villus sampling (CVS) can be offered as early as ten weeks of pregnancy and involves removing a sample of the placenta made by the baby and testing the cells. CVS carries a risk of causing a miscarriage that is between one-half to one percent.

Amniocentesis is generally offered between 16 and 18 weeks of pregnancy, but can sometimes be offered earlier. Two to three tablespoons of the fluid surrounding the baby is removed. This fluid contains fetal cells that can be tested. This test carries a risk of causing a miscarriage, which is less than 1%. Pregnant women and couples may choose prenatal testing in order to prepare for the birth of a baby that may have sickle cell disease.

Preimplantation genetic diagnosis (PGD) is a relatively new technique that involves in vitro fertilization followed by genetic testing of one cell from each developing embryo. Only the embryos unaffected by sickle cell disease are transferred back into the uterus. PGD is currently available on a research basis only, and is relatively expensive.

Treatment and management

There are several practices intended to prevent some of the symptoms and complications of sickle cell disease. These include preventive antibiotics, good hydration,

QUESTIONS TO ASK YOUR DOCTOR

- What are the risks and benefits of having a prenatal screening for sickle cell anemia?
- If my wife is a carrier of the gene for sickle cell anemia, what is the probability that one of our children will develop the disease?
- What is the genetic basis for sickle cell anemia?
- What is the status of current research on sickle cell anemia, and is a cure for the disease in the foreseeable future?

immunizations, and access to comprehensive care. Maintaining good health through adequate nutrition, avoiding stresses and infection, and getting proper rest is also important. Following these guidelines is intended to improve the health of individuals with sickle cell disease.

Penicillin

Infants are typically started on a course of penicillin that extends from infancy to age six. Use of this antibiotic is meant to ward off potentially fatal infections. Infections at any age are treated aggressively with antibiotics. Vaccines for common infections, such as pneumococcal pneumonia, are also recommended.

Pain management

Pain is one of the primary symptoms of sickle cell anemia, and controlling it is an important concern. The methods necessary for pain control are based on individual factors. Some people can gain adequate pain control through over-the-counter oral painkillers (analgesics). Other individuals, or painful events, may require stronger methods, which can include administration of narcotics. Alternative therapies may be useful in avoiding or controlling pain, including relaxation, hydration, avoiding extremes of temperature, and the application of local warmth.

Blood transfusions

Blood transfusions are not usually given on a regular basis but are used to treat individuals with frequent and severe painful events, severe anemia, and other emergencies. In some cases blood transfusions are given as a preventive measure, for example to treat spleen enlargement or prevent a second stroke (or a first stroke in an individual shown to be at high risk).

Regular blood transfusions have the potential to decrease formation of hemoglobin S, and reduce associated symptoms. However, there are limitations and risks associated with regular blood transfusions, including the risk of blood-borne infection and sensitization to proteins in the transfused blood that can make future transfusions very difficult. Most importantly, chronic blood transfusions can lead to iron overload. The body tends to store excess iron, such as that received through transfusions, in various organs. Over time, this iron storage can cause damage to various tissues and organs, such as the heart and endocrine organs.

Some of this damage can be prevented by the administration of a medication called desferoxamine that helps the body eliminate excess iron through the urine. Alternately, some individuals receive a new, nonstandard treatment called erythrocytapheresis. This involves the automated removal of sickle cells and is used in conjunction with a reduced number of regular transfusions. This treatment helps to reduce iron overload.

Hydroxyurea

Emphasis is being placed on developing drugs that treat sickle cell anemia directly. The most promising of these drugs since the late 1990s has been hydroxyurea, a drug that was originally designed for anticancer treatment. Hydroxyurea has been shown to reduce the frequency of painful crises and acute chest syndrome in adults, and to lessen the need for blood transfusions. Hydroxyurea, and other related medications, seem to work by inducing a higher production of fetal hemoglobin. The major side effects of the drug include decreased production of platelets, red blood cells, and certain white blood cells. The effects of long-term hydroxyurea treatment are unknown.

Bone marrow transplantation

Bone marrow transplantation has been shown to cure sickle cell anemia in some cases. This treatment is reserved primarily for severely affected children with a healthy donor whose marrow proteins match those of the recipient, namely a brother or sister who has inherited the same tissue type. Indications for a bone marrow transplant are stroke, recurrent acute chest syndrome, and chronic unrelieved pain.

Bone marrow transplantations tend to be the most successful in children; adults have a higher rate of transplant rejection and other complications. There is approximately a 10% fatality rate associated with bone marrow transplants done for sickle cell disease. Survivors face potential long-term complications, such as chronic graft-versus-host disease (an immune-mediated attack by

the donor marrow against the recipient's tissues), infertility, and development of some forms of cancer. A relatively recent advance in transplantation involves the use of donor stem cells obtained from cord blood, the blood from the placenta that is otherwise discarded following the birth of a new baby. Cord blood cells, as opposed to fully mature bone marrow cells, appear to be less likely to result in graft-versus-host disease in the recipient. This increases the safety and efficacy of the transplant procedure.

Surgery

Certain surgical interventions are utilized in the treatment of specific sickle cell-related complications. Removal of a dysfunctional gallbladder or spleen can often lead to improvements in health. Investigations are currently under way to establish the efficacy of hip coring surgery, in which a portion of affected bone is removed to treat avascular necrosis of the hip. The hope is that this may provide an effective treatment to alleviate some pain and restore function in the affected hip.

Psychosocial support

As in any lifelong, chronic disease, comprehensive care is important. Assistance with the emotional, social, family-planning, economic, vocational, and other consequences of sickle cell disease can enable affected individuals to better access and benefit from their medical care.

Prognosis

Sickle cell disease is characteristically variable between and within affected individuals. Predicting the course of the disorder based solely on genes is not possible. Several factors aside from genetic inheritance determine the prognosis for affected individuals, including the frequency, severity, and nature of specific complications in any given individual. The availability and access of comprehensive medical care also plays an important role in preventing and treating serious, acute complications, which cause the majority of sickle cell-related deaths. For those individuals who do not experience such acute events, life-expectancy is probably substantially greater than the average for all people with sickle cell disease. The impact of recent medical advances supports the hypothesis that current life expectancies may be significantly greater than those estimated in the early 1990s. At that time, individuals with SS disease lived to the early- to mid-40s, and those with SC disease lived into the upper 50s on average. With early detection and comprehensive medical care, most people with sickle cell disease are in fairly good health most of the time. Most individuals can be expected to live well into adulthood,

enjoying an improved quality of life including the ability to choose a variety of education, career, and family-planning options for themselves.

Simpson-Golabi-Behmel syndrome

Definition

Simpson-Golabi-Behmel syndrome (SGBS) is a rare X-linked recessive inherited condition. It causes general

overgrowth in height and weight. Individuals with SGBS also have characteristic facial features in childhood that tend to become less obvious in adulthood.

Description

SGBS is also known as Simpson dysmorphia syndrome (SDYS), bulldog syndrome, Golabi-Rosen syndrome, and dysplasia gigantism syndrome X-linked (DGSX). SGBS is a rare X-linked recessive inherited condition. Individuals with this condition have increased height and weight for their age; a broad, stocky appearance; a large protruding jaw; a short, broad nose; incomplete closure of the roof of the mouth (cleft palate); and broad, short hands and fingers. Individuals with SGBS are usually taller than average. The characteristic features usually become less apparent in adulthood. There are at least two genes for SGBS. Both genes are located on the X chromosome.

Genetic profile

SGBS is caused by an alteration (mutation) in one of two genes on the X chromosome. Chromosomes are units of hereditary material passed from a parent to a child through the egg and sperm. The information on the chromosomes is organized into units called genes. Genes contain information necessary for normal human growth and development. Each cell in the body usually contains 46 chromosomes, arranged as 23 pairs. Twenty-two pairs of chromosomes are the same in males and females. The twenty-third pair is the sex chromosomes: females have two X chromosomes and males have an X and a Y chromosome. There are two genes on the X chromosome that can cause SGBS. The first gene is responsible for making a protein called glypican-3 (GPC3). The exact role of GPC3 is not known but it is thought to play a role in growth and development. When the gene for GPC3 is altered, the signs and symptoms of SGBS result. A second candidate gene, which causes a more severe form of SGBS, is also located on the X chromosome. The function of this second gene is not known. Generally, individuals who have SGBS due to a gene alteration in the *GPC3* gene are said to have SGBS type 1 (SGBS1) and individuals who have SGBS due to an alteration in the second gene on the X chromosome are said to have SGBS type 2 (SGBS2).

SGBS is inherited as an X-linked recessive condition. With X-linked recessive conditions, males are usually more severely affected than females. Females have two copies of the *SGBS* gene (because they have two X chromosomes) while males have one copy of the *SGBS* gene (because they have one X chromosome). Females who have an alteration in one copy of the *SGBS* gene are said to be carriers of

Simpson-Golabi-Behmel Syndrome

X-Linked Recessive

Simpson-Golabi-Behmel syndrome: pedigree analysis chart (Gale)

SGBS. Generally, carriers show minimal or no effects of the altered gene because they have a second normal copy of the gene that is able to compensate for the altered copy. Since males have only one working copy of the *SGBS* gene to start, if that gene is altered, they will develop SGBS. When carrier females have children, they are at risk to have a child with SGBS. In each pregnancy, carrier females have a 25% chance of having a child (always a son) with SGBS and a 25% chance of having a child (always a daughter) whom is a carrier of SGBS. Males who are affected with SGBS cannot pass this condition to their sons (because their sons inherit the Y chromosome); however, all daughters of a male affected with SGBS will be carriers for the condition.

Demographics

SGBS is a rare inherited condition that primarily affects males from all ethnic groups. Female carriers for SGBS may show subtle features of the condition. The exact prevalence of SGBS remained unknown as of 2015, by which time only 130 people globally had been diagnosed with the condition.

Signs and symptoms

The spectrum of clinical features in SGBS is broad, ranging from very mild forms in carrier females to forms

that are lethal in the newborn male. SGBS affects the face, hands, chest, abdomen, genitals, internal organs, and overall growth.

Individuals with SGBS are larger than average at birth in height, weight, and head size. This overgrowth continues into adulthood, with affected males being taller than average. Final height in males ranges from 74 in. to 83 in. (188 cm to 210 cm). There are typical facial characteristics in affected males including widely spaced eyes, short nose, large mouth, large tongue, a groove in the lower lip, and teeth that do not align properly. Incomplete closure of the lip (cleft lip) and/or the roof of the mouth (cleft palate) can also occur. The large tongue and improperly aligned teeth can be a cause of speech difficulties.

The hands and feet of males with SGBS tend to be short and broad. Other hand abnormalities such as small nails, webbing of the skin between the fingers, and extra fingers/toes, is also common. Males with SGBS have extra nipples and some may have undescended testicles.

The internal organs are larger than average, particularly the liver, spleen, and kidneys. The kidneys may also have many cysts on them. A few individuals have been known to have lung and diaphragm abnormalities. Heart abnormalities can also occur in SGBS1 and have been a

cause of death in several individuals under two years of age. These include conduction defects causing arrhythmias. The stomach and intestines can also be affected, which may cause digestive problems. The bones may also be affected. Some individuals have an abnormal curving and twisting of the spine (scoliosis), extra ribs, and/or problems with the structure of the bones of the spine. The bony changes can be seen on x-ray but may not cause any symptoms.

Despite their large size, newborns with SGBS tend to be floppy babies with decreased muscle tone. Due to this low muscle tone, there are several features that can result such as mouth breathing, a deformity of the chest wall (pectus excavatum), shoulders that droop, hernias, and undescended testicles.

There is an increased risk to develop tumors of the kidney (Wilms tumor) in SGBS in early childhood. This risk appears to be greatest in individuals under two years of age.

Most individuals with SGBS are of average intelligence, although some degree of mental impairment has been observed in males who are more severely affected. Individuals with SGBS may have psychological difficulties dealing with their distinctive facial appearance and speech difficulties, which often give the false impression that they are mentally impaired.

Diagnosis

The diagnosis of SGBS is based on the presence of certain clinical features and in some cases may be confirmed through genetic testing. Not all affected individuals will have all of the features associated with SGBS. SGBS should be considered in an individual who is large in height, weight, and head circumference both before and after birth. Features of the condition that are almost always present include overgrowth, extra nipples, chest deformity, low muscle tone, and characteristic facial features including widely spaced eyes, short nose, large tongue and mouth, central groove of the lower lip, and improperly aligned teeth.

It may be possible to confirm the diagnosis of SGBS through genetic testing. Genetic testing for mutations in the *GPC3* gene causing SGB1 is available. Genetic testing involves obtaining a blood sample from the affected individual in order to look for the specific disease-causing mutation in the *GPC3* gene. Since not all individuals with SGBS have mutations in the *GPC3* gene, it may not be possible to confirm the diagnosis through genetic testing in all individuals suspected of having this condition. Genetic testing for the SGBS can be done on the developing baby before birth through amniocentesis or chorionic villus sampling if a mutation in the gene for

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance a needle is inserted either through the mother's vagina or abdominal wall and a sample of cells is collected from around the early embryo. These cells are then tested for chromosome abnormalities or other genetic diseases.

Chromosome—A microscopic thread-like structure found within each cell of the body and consists of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

GPC3 is first identified in an affected family member. Prenatal testing for parents of an affected individual should only be undertaken after the SGBS carrier status of the parents has been confirmed and the couple has been counseled regarding the risks of recurrence.

Treatment and management

The heart function of individuals with SGBS should be carefully monitored because it can be a cause of early death. Individuals with SGBS should be regularly followed by a heart specialist (cardiologist).

Individuals with SGBS are at increased risk to develop kidney tumors. They should be screened for possible kidney tumor development or other tumors of infancy for at least the first five years of life. Screening usually involves an ultrasound (sound wave picture) of the abdomen, including the kidneys.

The large tongue and improperly aligned teeth may lead to speech difficulties. Some individuals may require surgery to reduce the size of the tongue to aid with speech development or for cosmetic reasons. Individuals with speech difficulties may benefit from speech therapy.

QUESTIONS TO ASK YOUR DOCTOR

- What signs and symptoms are characteristic of Simpson-Golabi-Behmel syndrome?
- What information about Simpson-Golabi-Behmel syndrome can a genetic counselor provide me?
- What is the projected lifespan for an infant diagnosed with Simpson-Golabi-Behmel syndrome, and what factors affect that prognosis?
- Where can I obtain additional information about this genetic disorder?

Individuals with SGBS may benefit from psychological support and social support to help them reach an adequate level of self-esteem. They may also benefit from genetic counseling, which may provide them with further information on the condition itself and recurrence risks for future pregnancies.

Prognosis

The spectrum of clinical manifestations in SGBS is broad, varying from very mild forms in carrier females to infantile lethal forms in affected males. As many as 50% of males affected with SGBS die in the newborn period. The cause of this high mortality is not known but may be related to heart defects. In one reported family with a severe form of SGBS causing death in the newborn period, the responsible gene was not glypican-3 but the second candidate gene on the X chromosome.

Single genome sequencing

Definition

Single genome sequencing is an efficient method of sequencing the DNA of a single cell. Single genome sequencing is used to determine the variance between the cells of an individual and the cells of the norm for the indication of genetic-related pathologies such as cancers and autoimmune diseases.

Description

Since the completion of the Human Genome Project, more and more genome studies have been performed. The Human Genome Project mapped the blueprint of the code of human DNA (deoxyribonucleic acid). Any possible variance in a person's DNA can now be sequenced and compared to the normal genome, which can lead to an increased number of correct diagnoses, more effective treatment methods, and a better understanding of the relationship between DNA and genes and the interrelationship between genes themselves. As the need for information about and understanding of the human genome increases, so does the need for more time-efficient, cost-effective, and accurate methods of sequencing. Such methods include whole genome sequencing, next-generation sequencing, genome-wide association studies, Sanger sequencing (an older method), and a newer method known as single genome sequencing. These are all methods of sequencing that amplify DNA of cells, typically from blood or saliva, to determine the sequence of nucleotides that make up a string of DNA. This sequence is then compared to a normal sequence, and any variation can be linked to certain genes. Thus, an alteration in the structure or function of the human body can be pathologically identified.

Single genome sequencing is the sequencing of the genome of one cell using linear amplification. This

decreases the amount of bias that may arise in the non-linear sequencing seen in other sequencing methods and in turn increases the accuracy of the sequencing. Being able to sequence a single genome—the genome of a single cell—is extremely important in prenatal testing, when the zygote is only made up of a small number of cells relative to the size of a full-term fetus; for meiosis research; for the sequencing of a small number of tumor cells to determine possible treatment options; for studying the pathogenesis of cancer; and for testing a small amount of DNA in forensic analysis.

Studies have been done on mouse models between the three germ layers of the developing embryo with very good results. In the future this could prove instrumental for the sequencing of human embryos, as well as for further understanding of germ layers in embryology and potential genetic testing at early gestation. Single genome sequencing is also being used for assessing the frequency of drug resistance in patients with HIV-1. In addition to the use of single cell genome sequencing in the human body, single cell sequencing has also proven useful for the study of smaller organisms such as bacteria and archaea. Sequencing organisms such as these can give scientists a much better understanding on how they live and interact and of the evolutionary linkage between organisms.

Techniques

Single genome sequencing is currently performed using a technique developed in 2012 by Harvard University chemical biologist Sunney Xie and is termed MALBAC, which stands for multiple annealing and looping-based amplification cycles. MALBAC was developed after the false-positive and/or false-negative rates of previous methods such as single-nucleotide sequencing (SNS) were found to be too high due to high bias and the evaluation of incorrect strands of mRNA. Multiple displacement amplification (MDA), like MALBAC, was developed based on the mistakes of SNS.

A 2014 study investigated the differences between MALBAC and MDA and determined that MALBAC is the most useful technique because it has less bias and more coverage of the genome, making it the current technique of choice. MALBAC replicates a strand of DNA using color-coded primers (a separate primer for all four nucleotides—adenine, guanine, cytosine, and thymine). These primers are then separated by weight using a gel electrophoresis method to determine the sequence of the strand of DNA. This is typical of most genome sequencing methods. The single genome sequencing method differs from other methods because of the use of primers with two parts. The first part is an 8-nucleotide sequence that binds to the DNA being examined, starting the

KEY TERMS

Chromosome—A microscopic thread-like structure found within each cell of the body and consisting of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

De novo mutation—A genetic mutation that is seen for the first time in the affected person, not inherited from the parents.

DNA—Deoxyribonucleic acid, the main component in chromosomes and the substance that carries all genetic material.

Gene sequencing—The process of mapping the order of DNA or genetic material in an organism.

Genome—The entire DNA sequence of a cell or organism.

Human Genome Project—An international effort begun in 1990 and completed in 2003 to locate and identify the 100,000 genes on the 46 human chromosomes.

Nucleotide—A small molecule composed of three parts: a nitrogen base (a purine or pyrimidine), a sugar (ribose or deoxyribose), and phosphate; they serve as the building blocks of nucleic acids (DNA and RNA).

replication process, and the second part of the primer is a 27-nucleotide sequence with stop codons (a portion of the sequence that tells the DNA to stop replicating). The stop sequence cuts down on the amount of replications performed, decreasing the amount of time needed for the sequencing and also causing the DNA to loop back on itself. This prevents overcopying and major amplification and, therefore, makes it faster and easier to determine the sequence of the DNA being examined because only one original DNA sequence is replicated and coded. MALBAC is also used to see how quickly mutations accumulate, and the technique can determine variations in genes and chromosomes in the cells of an individual, helping researchers to understand *de novo* and other types of mutations and their impact on certain cells.

The MALBAC technique is an efficient technique for single genome sequencing, but it does have some drawbacks. The technique, although it allows for the most amount of duplication compared to other sequencing techniques (at 93%), only detects 66% of single-

nucleotide variants. In addition, the primer is error prone, potentially copying the original DNA incorrectly and presenting an increased number of single-nucleotide variants, such as in the event of a false positive. This is due to the fact that each cell has thousands of copies of each mRNA molecule but only two chromosomes.

Sirenomelia

Definition

Sirenomelia is a lethal birth defect of the lower body characterized by apparent fusion of the legs into a single lower limb. Other birth defects are always associated with sirenomelia, most commonly abnormalities of the kidneys, large intestines, and genitalia.

Description

This pattern of birth defects is believed to be associated with abnormal umbilical cord blood vessels. The normal fetus develops two umbilical arteries, which pump blood from the fetus to the placenta, and one umbilical vein, which returns blood from the placenta to the fetus. The umbilical arteries branch off the iliac

arteries in the pelvis. The iliac arteries supply the legs and pelvic organs such as the genitalia. Most babies with sirenomelia have only one umbilical artery and one vein. Rarely, a baby with sirenomelia can have the typical two arteries and one vein with occlusion (blockage) of one artery.

In sirenomelia, the one functional artery is larger than normal and branches from the aorta high in the abdomen. Below this umbilical artery, the aorta becomes abnormally narrow. This type of single umbilical artery is known as a vitelline artery because it is thought to arise from the primitive vitelline arteries early in the life of the embryo. The vitelline arteries normally fuse a few weeks after conception to form the arteries that supply the gastrointestinal system and genitourinary system (superior mesenteric, inferior mesenteric, and celiac arteries). If the normal umbilical arteries do not form correctly as branches from the iliac arteries, then a vitelline artery might persist.

The vitelline umbilical artery steals blood and nutrition from the lower body and diverts it to the placenta. This results in a small aorta and variable absence of the arteries that supply the kidneys, large intestine, and genitalia (renal, inferior mesenteric, and celiac arteries). Because of the loss of nutrition and blood flow, the lower limbs fail to form as separate limbs, the kidneys do not form or are malformed, the large intestine ends blindly in the abdominal cavity, the anus is imperforate, and the internal and external genitalia are absent or malformed.

The typical malformation of the lower limbs seen in babies with sirenomelia consists of apparent fusion of the legs. There is a spectrum of severity, with severe cases having one lower limb that tapers to a point with the absence of foot structures. In these severe cases there are only two bones present in the entire limb (a femur and presumably a tibia). On the mild end of the spectrum are babies with fusion of the skin of the lower limbs only. In these infants the feet may be fully formed with fusion at the ankles. All bones are fully formed and separate. Normally there are three bones in each leg—the femur in the upper leg (thigh) and the tibia and fibula in the lower leg (calf).

Other birth abnormalities of the upper body involving the heart, lungs, spine, brain, and arms can also be seen in this syndrome, but not in every affected individual. It is unknown at this time why a single umbilical artery could cause these changes.

Single umbilical artery occurs in about 1% of all live-born infants. In most of these infants the one umbilical artery is normally formed and not of vitelline origin. In these cases, the risk of other birth defects is low (about 8%). All infants born with a vitelline umbilical artery will

have other malformations, the most common being sirenomelia.

Genetic profile

All cases of sirenomelia have occurred in families as isolated cases, and there is no known genetic cause. It is possible that sirenomelia is an autosomal dominant condition and because it is lethal, all cases represent a new mutation. Alternatively, it might be a multifactorial trait in which multiple genes and environmental factors come together to cause this pattern of malformations. The fact that all cases have been isolated does not support this possibility. Sirenomelia is more common in monozygotic (identical) twin pregnancies. This may be indicative of an environmental cause.

Demographics

Sirenomelia is very rare, estimated to occur once in every 60,000 to 100,000 births. While the exact incidence in different populations is not known, sirenomelia has been reported worldwide in a variety of ethnic groups. It is known to be more common in monozygotic twin pregnancies (when compared to dizygotic (fraternal) twins) and in babies born to mothers with diabetes mellitus.

Signs and symptoms

Abnormalities associated with sirenomelia include the following:

- absence of the kidneys or malformed nonfunctioning kidneys
- blind ending colon and imperforate anus
- small, absent, fused, or poorly formed pelvic bones
- small, absent, or poorly formed internal and external genitalia
- fusion of the lower limbs along the inner leg, from skin only to complete fusion with the appearance of only one leg
- death from underdeveloped and immature lungs caused by oligohydramnios
- occasional birth defects in the upper body, including abnormalities in the heart, lungs, arms, spine, and brain

Diagnosis

The diagnosis is obvious at birth on examination of a baby, but prenatal diagnosis often occurs in the second trimester (weeks 13 through 26 of a pregnancy) by an ultrasound.

KEY TERMS

Aorta—The main artery located above the heart that pumps oxygenated blood out into the body. Many congenital heart defects affect the aorta.

Autosomal dominant—A pattern of inheritance in which only one copy of a defective gene on a nonsex chromosome is required for a disease or inherited trait to develop in an individual.

Iliac arteries—Arteries that supply blood to the lower body including the pelvis and legs.

Imperforate anus—Also known as anal atresia. A birth defect in which the opening of the anus is absent or obstructed.

Mermaid syndrome—Alternate name for sirenomelia, often used in older references.

Mutation—An inherited or de novo change in the DNA sequence of the genome.

Oligohydramnios—Reduced amount of amniotic fluid. Causes include nonfunctioning kidneys and premature rupture of membranes. Without amniotic fluid to breathe, a baby will have underdeveloped and immature lungs.

Stillbirth—The birth of a baby who has died sometime during the pregnancy or delivery.

Teratogenic—Any agent that can cause birth defects or intellectual disability in a developing fetus. Common teratogens are medications or other chemicals, but they also include infections, radiation, maternal medical condition, and other agents.

Ultrasound—An imaging technique that uses sound waves to help visualize internal structures in the body.

Treatment and management

Babies born alive with functioning kidneys may survive with appropriate surgical management. Operations to reconstruct the urinary and gastrointestinal outlet tracts are almost always needed. Other procedures and treatments depend on the extent of other birth defects. It appears that if a baby does survive, he or she will not have any mental delays.

Prognosis

Because of the birth defects involving the gastrointestinal tract and kidneys, sirenomelia is almost always fatal. About 50% of babies are stillborn (the baby has died before delivery) and 50% are live-born with survival

QUESTIONS TO ASK YOUR DOCTOR

- What is the cause of sirenomelia?
- What are the chances of survival for a baby born with sirenomelia?
- Can sirenomelia be detected by prenatal tests, such as ultrasound or chorionic villus sampling?
- What kind of information about sirenomelia is available from a genetic counselor?

lasting a few minutes to a few days. There have been at least two reported cases of sirenomelia patients that have survived beyond the first month of life. These infants had normal-functioning kidneys during their development.

Sjögren-Larsson syndrome

Definition

Sjögren-Larsson syndrome is an inherited disorder characterized by ichthyosis (scaly skin), speech abnormalities, mental retardation, and spasticity (a state of increased muscle tone with heightened reflexes). Severity is variable.

Description

Sjögren-Larsson syndrome is a rare genetic disorder inherited in an autosomal recessive fashion. First characterized by Swedish psychiatrist Torsten Sjögren in 1956 (and by Sjögren and Tage Larsson in 1957); they suggested that all Swedes with the syndrome are descended from one ancestor in whom a mutation (a genetic change) occurred about 600 years ago. The highest incidence of the disease occurs in northern Sweden.

In infancy, development of various degrees of scaling and reddened skin occurs, often accompanied by hyperkeratosis (thickening of the skin) on the outer skin layer. After infancy, skin on the arms, legs, and abdomen often is dark, scaly, and lacking redness. Seizures and speech abnormalities may accompany skin symptoms. About half of children affected with the syndrome experience degeneration of the pigment in the retina of the eye.

Sjögren-Larsson syndrome is also sometimes known as SLS; congenital ichthyosis-mental retardation-spasticity syndrome; ichthyosis-spastic neurologic disorder-oligophrenia syndrome; fatty aldehyde dehydrogenase deficiency (FALDH deficiency); fatty aldehyde dehydrogenase 10 deficiency (FALDH10 deficiency); or disorder of cornification 10 (Sjögren-Larsson Type). Sjögren-Larsson syndrome is not to be confused with Sjögren syndrome; it is sometimes called the T. Sjögren syndrome to distinguish it from Sjögren syndrome (characterized by dry eyes and mouth), which was described by Swedish ophthalmologist Henrick Sjögren.

Genetic profile

Inheritance of Sjögren-Larsson syndrome is autosomal recessive. In autosomal recessive inheritance, a single abnormal gene on one of the autosomal chromosomes (one of the first 22 "nonsex" chromosomes) from both parents can cause the disease. Both of the parents must be carriers in order for the child to inherit the disease since recessive genes are expressed only when both copies in the pair have the same recessive instruction. Neither of the parents has the disease (since it is recessive).

A child with both parents who carry the disease has a 25% chance of having the disease; a 50% chance of being a carrier of the disease (but not affected by the disease, having both one normal gene and one gene with the mutation for the disorder); and a 25% chance of receiving both normal genes, one from each parent, and being genetically normal for that particular trait.

The gene for the Sjögren-Larsson syndrome, *FALDH*, is located on chromosome number 17 in band 17p11.2. The gene mutation that is responsible for the disorder is located near the center of the chromosome and is strongly associated with the gene markers called D17S805 and ALDH10.

Demographics

Sjögren-Larsson syndrome is a rare disorder. The highest incidence occurs in northern Sweden. In Sweden, the prevalence of this syndrome is 1 in 250,000. All Swedes with the syndrome are believed to be descendants of one ancestor in whom a genetic change occurred about 600 years ago. (The phenomenon wherein everyone is descended from one person within what was once a tiny group of people is called founder effect.) The disease also occurs in members of families of other European, Arabic, and Native American descent, but is less prevalent. Sjögren-Larsson syndrome affects both males and females.

Signs and symptoms

There are several signs and symptoms of Sjögren-Larsson syndrome. The major features of the disorder are the following:

- **Skin:** In infancy, development of various degrees of scaling and reddened skin occurs (ichthyosis), often accompanied by hyperkeratosis (thickening of the skin) on the outer skin layer. After infancy, skin on the arms, legs, and abdomen is often dark and scaly and lacking redness. Bruises are present at birth or soon after.
- **Hair:** Hair may be brittle.
- **Extremities:** Joint contracture and hypertonia cause resistance of joints to movement and of muscles to stretching. Most individuals with the syndrome never walk.
- **Eyes:** About half of the individuals with this syndrome have retinitis pigmentosa (pigmentary degeneration of the retina). Glistening white or yellow-white dots on the retina (ocular fundus) are characteristic. They may be an early sign of the disease, presenting at age one to two, and may increase with age.

KEY TERMS

Contracture—A tightening of muscles that prevents normal movement of the associated limb or other body part.

Diplegia—Paralysis affecting like parts on both sides of the body, such as both arms or both legs.

Hypertonia—Excessive muscle tone or tension, causing resistance of muscle to being stretched.

Ichthyosis—Rough, dry, scaly skin that forms as a result of a defect in skin formation.

Retinitis pigmentosa—Progressive deterioration of the retina, often leading to vision loss and blindness.

Spasticity—Increased muscle tone, or stiffness, which leads to uncontrolled, awkward movements.

Tetraplegia—Paralysis of all four limbs. Also called quadriplegia.

- **Nervous system:** Spastic diplegia or tetraplegia (paralysis) affecting arms and/or legs. About half of the individuals with this disorder have seizures.
- **Urogenital system:** Kidney diseases may be associated with this syndrome.
- **Growth and development:** Individuals with the disorder tend to be unusually short in stature. Mental retardation is characteristic. Speech disorders may be present.

Speech abnormalities, mental retardation, and seizures usually occur during the first two or three years of life.

Diagnosis

The clinical features of Sjögren-Larsson syndrome are often distinctive, and a pattern of anomalies may suggest the diagnosis. In addition to ichthyosis and spasticity at birth, glistening white or yellow-white dots on the retina may be an early sign of the disease, presenting in the first or second year of life. If they occur, speech abnormalities, mental retardation, and seizures present during the first two or three years of life.

Laboratory findings are important in diagnosing Sjögren-Larsson syndrome. A laboratory test for deficiency of an enzyme (a protein that catalyzes chemical reactions in the human body) called fatty aldehyde dehydrogenase 10 (*FALDH10*) will determine presence of the disease. Sjögren-Larsson is due to a deficiency of *FALDH10*, and the gene for the Sjögren-Larsson syndrome is the same as the *FALDH10* gene.

Positive laboratory results for Sjögren-Larsson will include the following findings:

- hexadeconal elevated in fibroblasts
- fatty alcohol NAD+ deficient in Sjögren-Larsson syndrome fibroblasts
- fatty aldehyde dehydrogenase (FALDH) deficiency

Genetic counseling

Individuals with a family history of Sjögren-Larsson syndrome may benefit from genetic counseling to learn about the condition including treatments, inheritance, testing, and options available to them so that they can make informed decisions appropriate to their families. A child with both parents who carry the Sjögren-Larsson gene mutation has a 25% chance of having the disorder. Couples who have had one affected child have a 25% risk of having another child with the disorder in each pregnancy.

Prenatal testing

Families at risk to have a child with Sjögren-Larsson syndrome may have the option of prenatal diagnosis. DNA can be extracted from fetal cells obtained by either chorionic villus sampling (usually done at 12 weeks gestation) or amniocentesis (usually done at 16–18 weeks gestation) and tested to determine if the altered gene in the family is present. These techniques usually require that the alteration in the gene has been identified previously in an affected family member.

Chorionic villus sampling is a procedure to obtain chorionic villi tissue for testing. Chorionic villi are microscopic, finger-like projections that emerge from the chorionic membrane and eventually form the placenta. The cells of the chorionic villi are of fetal origin so laboratory analysis can identify a number of genetic abnormalities of the fetus. Because the villi are attached to the uterus, however, there is a chance that maternal tissue may be analyzed rather than the fetal cells. If the sample is too small, it may be necessary to repeat the procedure. In addition, the quality of the chromosome analysis is usually not as good with chorionic villus sampling as with amniocentesis. The chromosomes may not be as long, and so it may not be possible to identify some of the smaller bands on the chromosomes.

Amniocentesis is a procedure that involves inserting a thin needle into the uterus, into the amniotic sac, and withdrawing a small amount of amniotic fluid (a liquid produced by the fetal membranes and the fetus that surrounds the fetus throughout pregnancy). DNA can be extracted from the fetal cells contained in the amniotic

QUESTIONS TO ASK YOUR DOCTOR

- How common is Sjögren-Larsson syndrome in the general public outside of Sweden?
- What are the most common signs and symptoms associated with Sjögren-Larsson syndrome?
- What treatments are available to reduce the severity of this disorder?
- What is the prognosis for an infant diagnosed with Sjögren-Larsson syndrome?

fluid and tested for the specific mutation known to cause Sjögren-Larsson syndrome.

Treatment and management

Individuals with Sjögren-Larsson syndrome should be under routine health supervision by a physician who is familiar with the disorder, its complications, and its treatment. Supportive resources for individuals with Sjögren-Larsson syndrome and their families should be provided. Some clinical improvement has been reported to occur with fat restriction in the diet and supplementation with medium-chain triglycerides.

Other treatment of the disorder is generally symptomatic.

- For dermatologic symptoms, various skin-softening ointments are useful in reducing symptoms. Plain petroleum jelly may be effective, especially when applied while the skin is still moist, such as after bathing. Salicylic acid gel may also be effective. When using the ointment, skin is covered at night with an airtight, waterproof dressing. Lactate lotion is another effective treatment for the dermatologic symptoms.
- For ocular symptoms, regular care from a qualified ophthalmologist is important.
- To control seizures, anticonvulsant medications may be helpful.
- Speech therapy and special education services may be helpful.

Prognosis

Prognosis is variable depending upon the severity of the disease. Sjögren-Larsson syndrome does not generally lead to shortened lifespan.

Skeletal dysplasia

Definition

Skeletal dysplasias, also called osteochondrodysplasias, are a group of congenital abnormalities of the bone and cartilage that are characterized by short stature. There are more than 350 known types of skeletal dysplasia.

Description

Skeletal dysplasia, sometimes called dwarfism, is a disorder of short stature defined as height that is three or more standard deviations below the mean height for age,

race, and gender. Although all skeletal dysplasias involve disproportionately short stature, there are many other associated conditions.

Skeletal dysplasia may also have additional skeletal abnormalities, including:

- short arms and trunk, bowlegs, and a waddling gait
- skull malformations, such as a large head, cloverleaf skull, craniosynostosis (premature fusion of the bones in the skull), and wormian bones (abnormal thread-like connections between the skull bones)
- anomalies of the hands and feet, including polydactyly (extra fingers), "hitchhiker" thumbs, and abnormal fingernails and toenails
- chest anomalies, such as pear-shaped chest and narrow thorax

Other anomalies that may be present in individuals with skeletal dysplasia include:

- anomalies of the eyes, mouth, and ears, such as congenital cataract, myopia (nearsightedness), cleft palate, and deafness
- brain malformations, such as hydrocephaly, porencephaly, hydranencephaly, and agenesis of the corpus callosum
- heart defects, such as atrial septal defect (ASD), patent ductus arteriosus (PDA), and transposition of the great vessels (TGV)
- developmental delays and intellectual disability

Skeletal dysplasia encompasses more than 350 different specific diagnoses. Researchers and clinicians are still working to develop a consistent method of categorizing these disorders. In 1997, a standardized method for naming and classifying the skeletal dysplasias was proposed using information about the etiology of each disorder based on the genetic mutation or protein defect involved. Disorders that originate from similar or identical gene mutations were grouped together, and other categories were renamed in an attempt to create a more logical classification system. With so many unique disorders, categorizing the skeletal dysplasias will continue to evolve as new genetic mutations are identified. This system is still under consideration with clinicians attempting to choose between categories based on genetics and categories based on phenotype or clinical presentation.

Genetic profile

Skeletal dysplasia refers to a group of disorders characterized by abnormalities of bone and cartilage with similar modes of transmission: autosomal dominant and recessive and X-linked dominant and recessive.

KEY TERMS

Agenesis of the corpus callosum—An absence of the structure in the brain that connects the two hemispheres of the brain.

Atrial septal defect (ASD)—An abnormal opening between the two upper chambers of the heart (atria).

Autosomal—Genetic trait found on a chromosome that is not involved in determining sex.

Calcification—The process by which tissue becomes hardened by the depositing of calcium in the tissue.

Cleft palate—An abnormal opening, or cleft, between the roof of the mouth and the nasal cavity.

Cloverleaf skull—An abnormal, or cloverleaf, appearance to the skull caused by premature fusion of the bones in the skull of an infant.

Computed tomography (CT) scan; 3D CT scan—A diagnostic imaging procedure in which x-ray and computer technology are used to generate slices or cross-sectional images of the body; 3D CT scan produces three-dimensional images.

Congenital—Present at birth.

Congenital cataract—Clouding of the lens in the eye that is present at birth.

Craniosynostosis—An abnormal premature fusion of the bones of the skull in an infant.

Developmental delay—Not reaching the milestones of childhood development as expected.

Dominant—A genetic trait that is expressed when only one copy of it is present.

Echocardiogram (ECHO)—A diagnostic procedure that uses sound waves to produce images of the heart.

Epiphyses—Areas at the tip of the long bones that allow them to grow.

Gene mutation—A permanent change in genetic material that is transmittable.

Histological studies—Laboratory tests performed on tissue samples and cells.

“Hitchhiker” thumbs—A congenital anomaly of the thumb in which it is abnormally positioned at a right angle to the first joint.

Hydranencephaly—Congenital enlargement of the head and brain.

Hydrocephaly—An increase of cerebrospinal fluid in the brain.

Hypoplasia/hypoplastic—Small.

Kyphosis—Anomaly of the spine in which it curves backward.

Long bones—The femur in the leg and the humerus in the arm.

Lordosis—An abnormal curvature of the spine in which the lumbar, or lower section, is excessively curved.

Magnetic resonance imaging (MRI)—A diagnostic procedure that uses a combination of high-powered magnets, radio frequencies, and computers to generate detailed images of structures within the body.

Molecular analysis—Evaluation of molecules, tests that may identify single gene mutations.

Myopia—Nearsightedness.

Patent ductus arteriosus (PDA)—A congenital anomaly of the heart occurring when the ductus arteriosus (the temporary fetal blood vessel that connects the aorta and the pulmonary artery) does not close at birth.

Polydactyly—Extra fingers or toes.

Porencephaly—A congenital anomaly of the brain in which there are abnormal holes or cavities in the brain.

Prenatal ultrasound—An imaging test using high-frequency sound waves to create images of internal organs. Prenatal indicates the test is *performed on the* fetus while still in the womb.

Recessive—A genetic trait that is only expressed when another identical recessive gene is present.

Scapula—Shoulder blade.

Scoliosis—Abnormal curvature of the spine in which the spine curves to the side.

Short stature—Height of less than three standard deviations from the mean for age, race, and gender.

Short trunk—An abnormally short torso or body.

Sleep apnea—A potentially life-threatening condition in which the individual has episodes during sleep in which breathing temporarily stops.

Thorax—Chest cavity.

Transposition of the great vessels (TGV)—A congenital heart defect in which the major vessels of the heart are attached to the wrong chambers of the heart.

Wormian bones—A condition of the bones and cartilage in which growing bones are abnormally connected by thin string-like structures.

X-linked—A genetic trait that is carried on the X chromosome.

X-ray—An imaging test that uses beams of energy to create images of structures within the body.

There are approximately 350 different types of skeletal dysplasia; all have one or more unique genetic causes.

The most common forms of skeletal dysplasia and the genetic mutations that cause them include:

Achondrogenesis

This is a lethal form of skeletal dysplasia that is actually a group of disorders, type 1A, type 1B, and type 2. They are caused by mutations in the *TRIP11*, *SLC26A2*, and *COL2A1* genes, respectively. The features of these disorders include a small body, short limbs, and other skeletal abnormalities.

Achondroplasia

This is the most commonly reported type of skeletal dysplasia. It is caused by mutations in the *FGFR3* gene and is inherited through an autosomal dominant pattern. Individuals with this condition have an average height of 131 centimeters or 4.3 feet. Other features of this disorder include an average-size trunk, short arms and legs, an enlarged head (macrocephaly) with a prominent forehead, short fingers, and trident-appearing hands.

Diastrophic dysplasia

This type of skeletal dysplasia is caused by mutations in the *SLC26A2* gene, which has an autosomal recessive pattern of inheritance. A rare form of dwarfism, diastrophic dysplasia has characteristic features including short stature, very short arms and legs (mesomelic shortening), early-onset osteoarthritis, and joint contractions, which restrict movement. These joint problems can make it hard to walk and will worsen with age. Other features are clubfoot, scoliosis, cleft palate, and “hitchhiker thumb” (thumbs positioned at an angle).

Multiple epiphyseal dysplasia

This type of skeletal dysplasia is caused by mutations of the *COMP*, *COL9A1*, *COL9A2*, *COL9A3*, or *MATN3* genes and is most often inherited in an autosomal dominant pattern. In a few rare cases this disorder is transmitted in an autosomal recessive pattern, and the parents do not show symptoms. Features of the autosomal dominant type of multiple epiphyseal dysplasia include mild hip and knee disorders, arthritis (early-onset), and a waddling gait. Although most individuals with this disorder are of normal height, some may have mild short stature as adults. Most individuals are diagnosed during childhood; mild cases may not be diagnosed until adulthood. The recessive type is characterized by scoliosis and malformations of the hands, feet, and knees. About 50% of individuals with recessive multiple epiphyseal dysplasia are born with at least one additional abnormal

feature such as clubfoot, cleft palate, clinodactyly, ear swelling, or a double-layered patella (knee cap).

Pseudoachondroplasia

This type of skeletal dysplasia is caused by mutations in the *COMP* gene and is inherited in an autosomal dominant pattern. Individuals with this type have an average height of 116–120 centimeters or 3 feet 9 inches to 3 feet 11 inches. Other features include short arms and legs; a waddling walk; joint pain; osteoarthritis; hyperextensibility of the hands, knees, and ankles; limited range of motion at the elbows and hips; scoliosis; and normal facial features, head size, and intelligence.

Spondyloepiphyseal dysplasia (SED)

There are three types of this form of skeletal dysplasia:

- **X-linked spondyloepiphyseal dysplasia tarda** is caused by mutations in the *TRAPPC2* gene (aka *SEDL* gene) and has an X-linked inheritance pattern. It primarily affects boys and is characterized by normal growth until late childhood when growth is slowed and the features begin to develop. These features include shortened trunk and neck, unusually long arms, flattened vertebrae with hump-shaped bulges, and progressively thinning discs between vertebrae, scoliosis or kyphosis of the spine, hip abnormalities, curved legs, decreased movement in large joints, and early development of arthritis.
- **Spondyloepiphyseal dysplasia congenital** is a rare skeletal dysplasia that is caused by mutations in the *COL2A1* gene and is inherited in an autosomal dominant pattern. The short stature is present at birth, and other symptoms develop over time. Features are similar to X-linked spondyloepiphyseal dysplasia tarda with additional features that include mild abnormal facial features, vision and hearing impairment, and cleft palate.
- **CHST3-related skeletal dysplasia** (also called Larsen syndrome) caused by mutations in the *CHST3* gene with an unknown inheritance pattern. It is a rare condition with features similar to the other forms of spondyloepiphyseal dysplasia.

Thanatophoric dysplasia, type I and type II

This is a lethal form of skeletal dysplasia. It is caused by mutations in the *FGFR3* gene and is inherited in an autosomal dominant pattern. It is a severe skeletal disorder characterized by extremely short limbs and folds of extra skin on the arms and legs. Other features include a narrow chest, short ribs, underdeveloped lungs (pulmonary hypoplasia), and an enlarged head. There are two types, type I and type II. Type I is distinguished by curved thigh

bones and flattened bones of the spine (platyspondyly), while type II is characterized by straight thigh bones and a skull abnormality called a cloverleaf skull.

Demographics

Skeletal dysplasia is usually diagnosed at birth; however, some dysplasias may not be detected until much later. For this reason, it is difficult to determine the true incidence. The reported rate in the United States is 1 per every 4,000–5,000 births.

No one race is more likely to have skeletal dysplasia. The X-linked recessive disorders affect males almost exclusively, and X-linked dominant types are often lethal in males. Autosomal recessive and dominant transference affect males and females equally.

Signs and symptoms

The primary signs of skeletal dysplasia are abnormally shortened long bones in the legs and arms, short trunk, and abnormalities of the skull. In addition to the skeletal system, skeletal dysplasia disorders may also affect the heart, face, extremities, and joints. Some forms are lethal, and a significant number of fetuses with skeletal dysplasia die *in utero*.

Diagnosis

Many skeletal dysplasias can be diagnosed prenatally during routine prenatal ultrasound. If skeletal dysplasia is suspected, assessment and careful measurement of the extremities, thorax, spine, and facial structure can detect signs of the condition. Fetal movement may be decreased, and associated congenital heart and renal heart defects may be observed as well.

After birth, x-rays are the most effective diagnostic tool for evaluating the skeleton. A skeletal study includes views of the long bone, hands and feet, skull, chest, spine, and pelvis.

Abnormal x-ray results that may indicate a skeletal dysplasia include:

- dumbbell-shaped long bones
- bowing of the arms and legs
- oval-shaped translucencies in the femur and humerus
- scapula hypoplasia (small shoulder blades)
- abnormal pelvis
- vertebral abnormalities
- rib abnormalities, including cupping of the ends or shortening of the entire rib and stippled or spotted appearance to the cartilage

QUESTIONS TO ASK YOUR DOCTOR

- What type of skeletal dysplasia does my child have?
- What are the chances that we will have another child with skeletal dysplasia?
- Does my child need genetic testing?
- What are the most common symptoms of skeletal dysplasia?
- What treatments are recommended for this disorder?
- Are there organizations that provide support and information for families with skeletal dysplasia?

- epiphyses (growth centers of the long bones) abnormalities, including cone shape, stippled appearance, or an absence of calcification centers
- long bone fractures

Computed tomography (CT) scan and magnetic resonance imaging (MRI) are useful in assessing concurrent brain anomalies. MRI is useful in determining the extent and type of spinal abnormalities and compression present.

Three-dimensional CT scan is used to evaluate craniofacial anomalies prior to reconstructive surgery. MRI of the spine is also helpful in presurgical planning prior to surgical treatment of spinal and pelvic abnormalities.

Chromosome analysis may be performed to help determine the type of skeletal dysplasia an individual has. This is important so that other associated conditions can be diagnosed and treated as well.

Other diagnostic procedures that may be performed, including molecular analysis to identify single gene mutations, sleep studies to evaluate potentially life-threatening sleep apnea that is often a problem for individuals with skeletal dysplasia, histological studies to examine specific types of cells that identify some skeletal dysplasia forms, and an echocardiogram (ECHO) to evaluate the heart for defects.

Treatment and management

Treatment and management of children with skeletal dysplasia begins, in some cases, at birth. Neonatal resuscitation may be necessary for infants with certain more severe types of skeletal dysplasia in which the thoracic cavity is extremely small. This intervention can be life-saving.

The medical management of children with skeletal dysplasia begins at birth and continues into adulthood. Careful monitoring of height, weight, and head circumference is essential. Obesity is a risk for those with skeletal dysplasia. Excess weight can cause serious complications, including breathing difficulties such as sleep apnea, and may aggravate other spinal cord compression and joint instability found in many types of skeletal dysplasia.

Surgical treatment of skeletal dysplasia varies depending on the specific type present and the associated conditions. Sleep apnea may be treated by removal of the adenoids.

Spinal abnormalities, such as spinal cord compression, scoliosis, kyphosis, and lordosis, may be treated surgically. A spinal column fusion can relieve the stress on the spinal cord caused by malformations of the spinal column. In a spinal fusion, two or more vertebrae are fused together using bone grafts or metal rods.

In some individuals with short-limbed types of skeletal dysplasia, bone growth may be induced by a surgical bone-lengthening procedure. This procedure involves several surgeries and an extensive recovery period. The bone to be lengthened is cut. Leaving a narrow gap between the two pieces of bone, metal pins are inserted into the bone and the skin is closed. An external frame is attached to the pins and, gradually, the bone is pulled apart just enough to provide a small gap for the bone to grow into. As the bone grows, the space is widened and more bone grows. After the bone has healed, the pins are surgically removed. In some cases, as much as 6 in. (15 cm) has been added to leg length using this procedure.

Prognosis

While some skeletal dysplasias are lethal, most individuals with skeletal dysplasia have a normal life expectancy. The associated conditions may require medical and surgical treatment; however, these treatments are highly effective. Intelligence is usually normal. Most people with skeletal dysplasia have an excellent prognosis.

Smith-Fineman-Myers syndrome

Definition

Smith-Fineman-Myers syndrome (SFMS) is a rare and severe type of X-linked inherited intellectual impairment.

Description

Smith-Fineman-Myers syndrome is also known as Smith-Fineman-Myers-type intellectual impairment and Smith-Fineman-Myers-type X-linked intellectual impairment. SFMS results in severe intellectual impairment along with characteristic facial features and skeletal differences.

Genetic profile

Smith-Fineman-Myers syndrome is an X-linked disease. X-linked diseases map to the human X chromosome, a sex chromosome. Females have two X chromosomes, whereas males have one X chromosome and one Y chromosome. Because males have only one X chromosome, they require only one copy of an abnormal X-linked gene to display disease. Because females have two X chromosomes, the effect of one X-linked recessive disease gene is masked by the disease gene's normal counterpart on her other X chromosome.

In classic X-linked inheritance males are affected, presenting full clinical symptoms of the disease. Females are not affected. Affected fathers can never pass X-linked diseases to their sons. However, affected fathers always pass X-linked disease genes to their daughters. Females who inherit the faulty gene but do not show the disease are known as carriers. Female carriers of SFMS have a 50% chance to pass the disease-causing gene to each of their children. Each of a female carrier's sons has a 50% chance to display the symptoms of SFMS. None of a female carrier's daughters would display symptoms of SFMS.

Some patients with SFMS have been found to have a mutation in the *ATRX* gene, on the X chromosome at position Xq13.3. *ATRX* is also the disease gene for several other forms of X-linked intellectual impairment, such as X-linked alpha-thalassemia/intellectual impairment syndrome, Carpenter syndrome, Juberg-Marsidi syndrome, and X-linked intellectual impairment with spastic paraplegia. A 2008 report mapped the causative gene in a large Chinese family with SFMS to *Xq25*.

Demographics

SFMS affects only males and is very rare. As of 2015, fewer than 20 cases had been reported in the medical literature. SFMS has been reported in brothers of affected boys.

Signs and symptoms

SFMS visibly affects the skeletal and nervous systems and results in an unusual facial appearance. The genitals may also show effects ranging from mild (e.g., undescended testes) to severe (leading to female gender assignment).

Skeletal features

Boys with SFMS have short stature and a thin body build. Their heads are small and may also be unusually shaped. Scoliosis and chest abnormalities have been reported to occur with SFMS. X-rays may show that their

KEY TERMS

Spasticity—Increased muscle tone, or stiffness, which leads to uncontrolled, awkward movements.

Tone—A term used to describe the tension of muscles. Increased tone is increased tension in the muscles.

bones have characteristics of the bones of people younger than they are. Hands are often short with unusual palm creases and short, unusually shaped fingers. Fingernails may be abnormal. Foot abnormalities and shortened or fused toes have also been reported.

Neurological features

Boys with SFMS exhibit severe intellectual impairment. Restlessness, behavior problems, seizures, and severe delay in language development are common. Boys with SFMS may be self-absorbed with reduced ability to socialize with others. Affected boys show reduced muscle tone as infants and young children. Later, muscle tone and reflexes are abnormally increased, causing spasticity.

Boys with SFMS may display cortical atrophy, or degeneration of the brain's outer layer, on brain imaging studies. Cortical atrophy is commonly found in older unaffected people. When cortical atrophy is found in younger people it is typically due to a serious brain injury. Brain biopsies of two patients with SFMS have been normal.

Facial features

SFMS is associated with unusual facial features including a large mouth with a drooping lower lip, prominent upper jaw and front teeth, and an underdeveloped chin. Cleft palate has been reported in one set of affected twins. Eyes are widely spaced with drooping eyelids. Skin may be lightly pigmented with multiple freckles.

Diagnosis

Assessment for any type of intellectual impairment should include a detailed family history and thorough physical exam. Brain and skeletal imaging through CT scans or x-rays may be helpful. A chromosome study and certain other genetic and biochemical tests help to rule out other possible causes of intellectual impairment.

Diagnosis of SFMS has traditionally been based on the visible and measurable symptoms of the disease. Until

QUESTIONS TO ASK YOUR DOCTOR

- I recently read about a child with Smith-Fineman-Myers syndrome. How common is this disease?
- Other than intellectual impairment, what symptoms are associated with this disorder?
- What is the lifespan of an individual with Smith-Fineman-Myers syndrome?
- Why do there not seem to be any clinical trials for the treatment of Smith-Fineman-Myers syndrome?

2000, SFMS was not known to be associated with any particular gene. Scientists do not yet know if other genes may be involved in some cases of this rare disease. Genetic analysis of the *ATRX* gene may, however, prove to be helpful in diagnosis of SFMS.

Treatment and management

Treatment for SFMS is based on the symptoms each individual displays. Seizures are controlled with anticonvulsants. Medications and behavioral modification routines may help to control behavioral problems.

Prognosis

Intellectual disability is severe, but it does not seem to get worse with age. Lifespan does not appear to be shortened.

Smith-Lemli-Opitz syndrome

Definition

Smith-Lemli-Opitz syndrome (SLOS) is an autosomal recessive syndrome characterized by microcephaly, intellectual disability, short stature, and major and minor malformations; it is caused by a mutation in the gene that encodes the enzyme 7-dehydrocholesterol reductase (*DHCR7*), which is required for cholesterol metabolism.

Description

David W. Smith, John M. Opitz, and Luc Lemli first characterized SLOS in 1964. The syndrome has variable characteristics marked mainly by short stature, intellectual disability, microcephaly, postaxial polydactyly (an extra digit on the little finger side of the hand or the little toe side of the foot), cleft palate, cardiovascular defects, genital malformations, and other abnormalities associated with altered cholesterol metabolism. In 1993, scientists discovered that children with SLOS have a metabolic disorder that prevents the synthesis of sufficient amounts of cholesterol to support normal growth and development.

Sometimes the severe form of the disease is called SLOS type II but research has shown that type II is not biochemically distinct from other forms of SLOS. Rather, it represents a more severe expression of the SLOS phenotype.

SLOS is also known as Smith syndrome, RSH syndrome, and RSH/Smith-Lemli-Opitz (RSH/SLO) syndrome. The designation RSH represents initials of the surnames of the first three patients in whom the syndrome was first observed.

Genetic profile

SLOS is inherited in an autosomal recessive manner. In autosomal recessive inheritance, mutated genes for *DHCR7* must be inherited from both parents for the traits associated with the disease to be present. Parents of children with SLOS are carriers of the disorder and are most often not affected themselves, as they have one functional and one mutated *DHCR7* gene.

A child with both parents as carriers for SLOS has a 25% chance of having the disease; a 50% chance of being a carrier of the disease; and a 25% chance of receiving both normal genes and being genetically normal for that particular trait.

The protein product of the *DHCR7* gene is required for cholesterol synthesis. Cholesterol is a major component of lipid membranes in animals that supports membrane integrity and fluidity. Additionally, cholesterol is a precursor substrate for steroid hormones that are required for sexual differentiation and development, as well as multiple functions in metabolic regulation.

Demographics

SLOS occurs in approximately 1 in 20,000 to 30,000 births in populations of northern and central European background. Evidence suggests that there is a higher frequency of SLOS in people of northern European ancestry and a lower frequency in people of Asian or African background.

Because of the presence of recognizable genital abnormalities, males are more likely than females to be evaluated for a diagnosis of SLOS. Therefore, the occurrence of the disease among females is less understood.

Signs and symptoms

The following are features of SLOS:

- Nearly 90% of people with SLOS have microcephaly.
- Nearly all people with SLOS have moderate to severe intellectual disability.
- Other neurologic findings are less common. These include seizures and muscle hypotonia.
- Characteristic facial features include narrowing at the temples, epicanthal folds (skin fold of the upper eyelid covering the inner corner of the eye), down-slanting eyes, drooping upper eyelids, anteverted nares (nostrils that tilt forward), and abnormal smallness of the jaw (micrognathia). Cleft palate is present in 40%–50% of people with SLOS, and about 20% have congenital cataracts. Strabismus, poor tracking, opsoclonus (impairment of eye movements), and optic nerve

KEY TERMS

Anomaly—Different from the normal or expected. Unusual or irregular structure.

Cleft palate—A congenital malformation in which there is an abnormal opening in the roof of the mouth that allows the nasal passages and the mouth to be improperly connected.

Congenital—Refers to a disorder that is present at birth.

Cryptorchidism—A condition in which one or both testes fail to descend normally.

Hypospadias—An abnormality of the penis in which the urethral opening is located on the underside of the penis rather than at its tip.

Hypotonia—Reduced or diminished muscle tone.

Microcephaly—An abnormally small head.

Polydactyly—The presence of extra fingers or toes.

Strabismus—An improper muscle balance of the ocular muscles resulting in crossed or divergent eyes.

Syndactyly—Webbing or fusion between the fingers or toes.

demyelination (deterioration) are other possible ophthalmologic manifestations.

- Cardiac abnormalities are present in about 35%–40% of patients with SLOS. Increased incidence of atrioventricular canal defects and anomalous pulmonary venous return is seen in people with SLOS.
- Urogenital anomalies are frequent. Kidney hypoplasia (smaller than normal kidneys) or dysplasia (abnormal development) of the kidneys occurs in about 40% of people with SLOS. Genital anomalies of variable severity may include hypospadias and/or bilateral cryptorchidism, which occur in about half of reported cases, and a small penis. Many biologically male individuals with severe manifestations of SLOS have undermasculinization of the external genitalia, resulting in female external genitalia (sex reversal). Abnormalities in the uterus and vagina have been noted in females.
- Syndactyly of the second and third toes occurs frequently. Postaxial polydactyly is present in 25%–50% of all cases. Other abnormalities affecting the hands and feet may be present.
- Short stature is common. Limbs and neck are shorter than normal.

Growth may be retarded prenatally, and children born with SLOS will often show failure to thrive, have abnormal sleep patterns, and have photosensitivity.

Diagnosis

The clinical features of SLOS are often distinctive, and a pattern of congenital anomalies can suggest a diagnosis. The diagnosis of SLOS relies on clinical suspicion and detection of abnormally elevated serum concentration of 7-dehydrocholesterol (7-DHC) or an elevated 7-dehydrocholesterol:cholesterol ratio. Serum concentration of cholesterol is usually low, with cholesterol levels less than 50 mg/dl (normal is greater than 100 mg/dl). Cholesterol is an essential building block of all cell membranes and the white matter of the brain; SLOS appears to be caused by abnormally low levels of the enzyme 7-DHC-reductase, which converts 7-DHC into cholesterol. Children with SLOS with the lowest cholesterol levels tend to have the most severe forms of the disorder and often die at birth or in the first few months. In about 10% of patients, cholesterol is in the normal range and is considered to be an unreliable marker for screening and diagnosis.

Molecular genetic testing of the *DHCR7* gene is not generally available, but since the molecular structure of the *DHCR7* has been identified, the possibility now exists for DNA-based testing for diagnosis and genetic counseling. Currently such testing is available on a research basis only.

Genetic counseling

Carrier detection is problematic using biochemical testing because carriers usually have normal 7-DHC and cholesterol levels. Although not widely available, carrier testing is possible by measurement of 7-DHC or enzyme levels in cultured cells. More accurate DNA testing for *DHCR7* mutations is not currently available but it is anticipated in the near future. Couples who have had one affected child have a 25% risk of having a child with SLOS in each pregnancy.

Prenatal testing

For couples known to be at 25% risk for having a baby with SLOS, testing is available to assist in prenatal diagnosis. Prior testing of family members is usually necessary for prenatal testing.

Either chorionic villus sampling (CVS) or amniocentesis may be performed for prenatal testing. Abnormal levels of 7-dehydrocholesterol in amniotic fluid or CVS are diagnostic of SLOS. CVS can be performed at 10–12 weeks gestation, while amniocentesis testing is performed after 15 weeks.

Abnormal concentration of 7-dehydrocholesterol levels in tissue obtained from CVS or in amniotic fluid is diagnostic in the prediction of prenatal cases of SLOS.

For low-risk pregnancies, in which there is no family history of SLOS, certain findings in the fetus might prompt consideration of the syndrome. The combination of low unconjugated estriol levels, low HCG, and low alpha-fetoprotein on routine maternal serum testing at 16–18 weeks gestation might suggest the possible diagnosis of SLOS. Findings on ultrasound examination such as cardiac defects, cleft palate, genital abnormalities, or growth retardation might be suggestive, prompting consideration of a 7-dehydrocholesterol assay of amniotic fluid.

Treatment and management

It is not known what role the elevated levels of 7-DHC and other sterol precursors—not usually present in significant concentrations in the plasma—play in the pathogenesis of SLOS. Children with SLOS should be under routine health supervision by a physician who is familiar with SLOS, its complications, and its treatment. Since a common complication of the syndrome is pneumonia, it should be treated with appropriate antibiotics when it occurs. Special education services and physical therapy may be recommended as needed.

Infant care

A physician familiar with the range of problems seen in infants with SLOS is important for appropriate health supervision and anticipatory guidance. Poor feeding and problems with weight gain are common in infants with SLOS; many infants have difficulties with sucking and/or swallowing and may require alternative feeding. A diagnosis of pyloric stenosis (caused by a thickening and spasm of the stomach outlet) should be considered for those with frequent vomiting or apparent gastroesophageal reflux. Particular attention should also be given to the stooling pattern, abdominal distention, or other signs of possible obstruction, particularly in children with more severe phenotype since these may indicate Hirschsprung disease (absence of nerves in the colon).

Surgical treatment

Surgical management of congenital anomalies such as cleft palate, congenital heart disease, and genital anomalies for the more severely affected infants need to be considered as they would in any other infant with a severe, usually lethal disorder. Even with vigorous intervention, children with multiple major manifestations of SLOS are believed to have decreased rates of survival.

QUESTIONS TO ASK YOUR DOCTOR

- Please explain the genetic basis of Smith-Lemli-Opitz syndrome.
- What are the most serious medical consequences of this genetic disorder?
- What is the prognosis for Smith-Lemli-Opitz syndrome?
- Where can I find additional information about this genetic disorder?

Dietary supplementation

Because SLOS is a cholesterol deficiency syndrome, research trials have recently included dietary cholesterol supplementation. An increase in total caloric intake and an increase in cholesterol intake hold promise for treatment of SLOS, but the research is still preliminary. Benefits reported in these studies include improved growth in children with SLOS, possible enhanced developmental progress, reduced dermatologic problems, and improved behavior. No harmful side effects of cholesterol supplementation have been documented.

Prognosis

Prognosis is variable depending upon the severity of the disease. Children with SLOS who have multiple major malformations are believed to have decreased rates of survival, even with vigorous intervention.

Smith-Magenis syndrome

Smith-Magenis syndrome

Definition

Smith-Magenis syndrome (SMS) is a relatively rare genetic disorder characterized by a specific pattern of physical, behavioral, and developmental features. First described in 1982 by Ann C. M. Smith (a genetics counselor) and colleagues, the syndrome results from a deletion on chromosome 17, specifically referred to as deletion 17p11.2.

Description

Until the mid-1990s, SMS was not a well-known disorder, even among genetics experts; the chromosome deletion is small (a microdeletion) and difficult to detect. Most individuals are not diagnosed until they receive specialized genetic tests, usually in mid-childhood or adulthood.

Smith-Magenis syndrome causes multiple birth defects (congenital abnormalities) as well as moderate to severe intellectual disabilities. The clinical manifestations of SMS vary. However, a number of characteristic physical features, developmental delays, and behavioral problems occur in all patients with the disorder. According to some researchers, the extent of the chromosomal deletion may account for the variable severity of symptoms.

The most common and clinically recognizable features of those with SMS include mild to moderate brachycephaly (short, wide head), flat midface, intellectual disability, and short, broad hands. Common but less consistent physical abnormalities include a prominent forehead, protruding jaw, and low-set ears. The major clinical features and the specific abnormalities of SMS are the most obvious diagnostic clues to the disorder. Some experts believe that with more research on this syndrome, SMS may be determined to be a relatively common cause of intellectual disabilities.

Genetic profile

Although SMS is caused by a deletion of genetic material from a portion of chromosome 17, the syndrome usually does not run in families. In most cases, the deletion occurs accidentally at conception when an abnormal sperm or egg from one parent unites with a normal sperm or egg from the other parent. The abnormal sperm or egg contains the missing chromosomal material. These abnormal sperm or eggs are present in everyone; however, the risk of an abnormal conception increases significantly with the parents' ages.

Research has shown a random parental origin of deletion, suggesting that SMS is likely a contiguous gene deletion syndrome. Contiguous gene syndromes are conditions that occur as a result of microdeletions or microduplications involving several neighboring genes.

Demographics

Although the exact incidence of SMS is not known, the disorder is rare and estimated to occur in approximately 1 in 25,000–50,000 live births. Only about 150 cases have been identified worldwide from a diversity of ethnic groups. The ages of those affected ranges from neonates to individuals in their 70s. About an equal number of males and females are affected by the disorder.

Signs and symptoms

Although there are many features associated with SMS, not every individual exhibits all of these features. The following is a common list of traits that have been reported:

- distinct facial features: brachycephaly, flat midface area, prominent forehead, eyelid folds, broad nasal bridge, protruding jaw, and low-set ears
- brachydactyly (short fingers and toes)
- short stature
- hoarse, deep voice
- speech delay
- learning disabilities

KEY TERMS

Brachycephaly—An abnormal thickening and widening of the skull.

Brachydactyly—Abnormal shortness of the fingers and toes.

Chromosome—A microscopic thread-like structure found within each cell of the body that consists of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Contiguous gene syndrome—Conditions that occur as a result of microdeletions or microduplications involving several neighboring genes.

FISH (fluorescent in situ hybridization)—Technique used to detect small deletions or rearrangements in chromosomes by attempting to attach a fluorescent (glowing) piece of a chromosome to a sample of cells obtained from a patient.

Melatonin—A sleep-inducing hormone secreted by the pineal gland.

Phenotype—The physical expression of an individual's genes.

Scoliosis—An abnormal, side-to-side curvature of the spine.

- chronic ear infections
- intellectual disabilities (typically in the 50–60 range for IQ)
- poor muscle tone and/or feeding problems in infancy
- eye disorders
- sleep disturbances
- insensitivity to pain
- behavioral problems: hyperactivity, head banging, hand/nail biting, skin picking, pulling off fingernails and toenails, explosive outbursts, tantrums, destructive and aggressive behavior, excitability, arm hugging/squeezing when excited

- engaging and endearing personality

Less common symptoms include:

- heart abnormalities
- scoliosis (curvature of the spine)
- seizures
- urinary tract abnormalities
- abnormalities of the palate, cleft lip

- hearing impairment

Diagnosis

Although SMS is generally believed to be underdiagnosed, with increased professional awareness and improved methods of testing, the number of individuals identified increases annually. In diagnosing the disorder, the characteristic behavioral features of SMS are usually recognized before the facial features, often leading to a delay in diagnosis.

Phenotype (physical features) identification

Facial abnormalities evolve over time and are more subtle in early childhood. Thus, diagnosis of SMS at birth or in infancy is infrequent and is usually made by chance when abnormal facial features suggest a diagnosis of Down syndrome (a more commonly known congenital abnormality caused by an extra chromosome 21) and chromosome testing reveals the SMS 17p11.2 deletion.

The phenotypic overlap of SMS with Down syndrome, particularly in early life, can be striking. Both conditions share a number of features, including brachycephaly, upward-slanting eyes, a short and broad nose, midface flattening, eye disorders, short stature, small hands and feet, and poor muscle tone. However, age evolves the somewhat coarse appearance of the face, and by young adulthood, the phenotype of the disorder is well developed and striking. Familiarity with the clinical manifestations of both genetic disorders improves the likelihood of early diagnosis and intervention.

High-resolution chromosome analysis

The diagnosis of SMS is often confirmed through a blood test called a high-resolution chromosome analysis, which is generally performed for the evaluation of developmental delays or congenital abnormalities. In the case of microdeletions, the chromosome deletions are so small that often they cannot be detected by chromosome analysis alone. In an older child, however, the phenotype is distinctive enough for a clinical diagnosis to be made by an experienced clinician prior to the chromosome analysis.

FISH analysis

If chromosome analysis is inconclusive, FISH (fluorescent in situ hybridization) is the test of choice to document the SMS deletion because it has a high degree of accuracy. In FISH analysis, which has become a standard molecular test, denatured DNA (DNA altered by a process that separates the complementary strands within the DNA double helix structure) is kept in place in the chromosome and is then hybridized (mixed) with RNA or DNA

QUESTIONS TO ASK YOUR DOCTOR

- How and at what stage in a child's life can Smith-Magenis syndrome be diagnosed?
- Are there medications or procedures that can be used to slow progress of the disease or otherwise keep it under control?
- What is the long-term prognosis for a child who has been diagnosed with Smith-Magenis syndrome?
- Are there organizations from which I can obtain more information about this genetic disorder?

(extracted from another source) to which a fluorescent tag has been attached. The advantage of maintaining the DNA in the chromosome is that the specific chromosome (or chromosomes) containing the gene of interest can be identified by observing, under a microscope, the location of the fluorescence. Combining FISH and standard chromosome analysis can characterize the structural rearrangements and marker chromosomes.

In SMS, predictive or prenatal screening is an unlikely outcome of identifying the flawed gene because the disease is so rare and does not run in families. Instead, researchers hope to determine how the extent of the microdeletion on chromosome 17 is related to the various signs and symptoms of SMS.

Treatment and management

There is no cure for SMS because the disorder is so complex and has received relatively little research attention. Therefore, managing symptoms becomes a priority in those diagnosed with the disorder.

A child with SMS typically displays self-injurious behavior as well as attention-seeking outbursts and aggressive behavior. Medications such as carbamazepine (an anticonvulsant) may be prescribed for severe behavioral problems associated with SMS. However, in most cases, drugs to help control or modify behavior or increase attention span have been found to be minimally effective. Any pharmacologic treatment of SMS remains individual, and several drugs may need to be tested to optimize results.

In addition to behavioral problems, children with SMS tend to have speech delays. Therefore, speech therapy, starting as early as possible, is typically beneficial. Most children learn to communicate verbally, and either with sign language or gestures.

Since children with SMS are often easily distracted, they tend to do better in small, focused classroom settings in which there are no more than five to seven children. If the classroom is larger, competition for the teacher's attention increases, along with the probability of behavioral problems. These children also seem to respond to consistency, structure, and routines; changes in routine can provoke behavioral outbursts and tantrums.

Children with SMS have problems with sequential processing, which makes counting, mathematical skills, and multi-step tasks especially difficult. They tend to learn best with visual cues (such as pictures illustrating tasks). Also, since they have a fascination with electronics, the use of computers and other technology may be effective teaching tools in these children. Generally very responsive to affection, praise, and other positive emotions, children with SMS usually enjoy interacting with adults. A parent or teacher's positive response can often motivate a child to learn.

More than half of children with SMS have sleep disturbances such as daytime sleepiness, difficulty falling asleep at night, nocturnal awakening, decreased sleep time, and abnormalities in REM (rapid eye movement) sleep. These disturbances are due to abnormal melatonin metabolism. Melatonin is a sleep-inducing hormone secreted by the pineal gland in the brain. Therefore, a locking mechanism on the door may be helpful in preventing the child from wandering out of his or her bedroom at night. Also, a night-time dose of melatonin has been recommended for some children and adults with SMS.

Some experts have suggested that every individual with SMS have annual examinations for thyroid function, scoliosis, and eye problems. If any of these tests is abnormal, intervention and further clinical evaluation is appropriate.

Prognosis

Although there is no medical prevention or cure for SMS, early diagnosis gives parents time to learn about and prepare for the challenges of the disease. Although there is insufficient data regarding the average life expectancy of those diagnosed with SMS, some individuals have lived well into their 70s.

Sotos syndrome

Definition

Sotos syndrome is a genetic condition causing excessive growth and a distinctive head and facial appearance. It has in the past been known as cerebral gigantism. It is often accompanied by delayed development, low muscle tone, and impaired speech.

Description

Sotos syndrome was first described in 1964 and is primarily classified as an overgrowth syndrome, which means that the individual affected with it experiences rapid growth. A number of different symptoms occur in Sotos syndrome; however, it primarily results in rapid growth beginning in the prenatal period and continuing through the infancy and toddler years and into the elementary school years. It is also strongly associated with the bones developing and maturing more quickly (advanced bone age), in a distinctive-appearing face, and in developmental delay.

The excessive prenatal growth often results in the newborn being large with respect to length and head circumference; weight is usually average. The rapid growth continues through infancy and into the youth years with the child's length/height and head circumference often being above the 97th percentile, meaning that out of 100

children of the same age, the child is longer/taller and has a larger head than 97 of the children. The rate of growth appears to decrease in later childhood and adolescence and final heights tend to be within the normal ranges.

The facial features of individuals with Sotos syndrome change over time. In infants and toddlers, the face is round with the forehead being prominent and the chin small. As the child grows older and becomes an adolescent, the face becomes long with the chin being more prominent, usually with a pointed or square shape. In adults, faces are usually long and thin. The head remains large from birth through adulthood.

Hypotonia is present at birth in nearly every child with Sotos syndrome. Hypotonia means that there is significantly less tone in the muscles. Bodies with hypotonia are sometimes referred to as “floppy.” Muscle tone improves as the child grows older but even in adults, it is still present to some degree. Hypotonia affects many aspects of the baby’s development. It can cause difficulty in sucking and swallowing and many babies are diagnosed with failure to thrive in the newborn period. This, however, usually lasts for about three to four months and then goes away. Hypotonia makes attaining fine motor skills (grasping, playing with toys, babbling) and gross motor skills (rolling, crawling, walking) difficult and these developmental milestones are usually delayed. Speech is also affected by hypotonia but as the child grows older and the hypotonia resolves or goes away, speech improves. Although the child may have delayed development, intellect typically is borderline to normal. Special attention may be needed in certain subjects, such as reading comprehension and arithmetic. Severe mental retardation is rarely seen.

There are a number of other features that have been associated with Sotos syndrome including jaundice in

Sotos syndrome: pedigree analysis chart (Gale)

KEY TERMS

Advanced bone age—The bones, on x-ray, appear to be those of an older individual.

Congenital—Refers to a disorder that is present at birth.

Failure to thrive—Significantly reduced or delayed physical growth.

Jaundice—Yellowing of the skin or eyes due to excess of bilirubin in the blood.

Karyotype—A standard arrangement of photographic or computer-generated images of chromosome pairs from a cell in ascending numerical order, from largest to smallest.

Tumor—An abnormal growth of cells. Tumors may be benign (noncancerous) or malignant (cancerous).

the newborn period, coordination problems, and a tendency for clumsiness. Behavioral problems and emotional immaturity are commonly reported. About half of the children with Sotos syndrome will experience a seizure associated with fever. Dental problems such as early eruption of teeth, excessive wear, discoloration, and gingivitis are common. Teeth may also be aligned incorrectly due to changes in the facial structure.

Infections tend to develop in the ear, upper respiratory tract, and urinary tract. In some children, hearing may be disrupted due to recurrent ear infections and in these situations, a referral to an otolaryngologist (a doctor specializing in the ear, nose, and throat) may be necessary for assessment of hearing. Urinary tract infections occur in about one out of five children with Sotos syndrome. These have been associated with structural problems of the bladder and ureters; consequently, if urinary tract infections occur, the child should undergo further evaluation.

Congenital heart problems and development of tumors have been reported in individuals with Sotos syndrome. However, the information regarding the actual risks of these problems is not definitive and medical screening for these conditions is not routinely recommended.

Genetic profile

Sotos syndrome is for the most part a sporadic condition, meaning that a child affected by it did not inherit it from a parent. In a very few families, autosomal dominant inheritance has been documented, which means that both a parent and his/her child is affected by Sotos syndrome.

A Japanese research team found that there is a fault in the *NSD1* gene in most children with Sotos syndrome. Other causes have not been identified.

Demographics

Sotos syndrome has been found to occur in between 1 in 10,000 and 1 in 14,000 newborns. Sotos syndrome occurs in both males and females and has been reported in several races and countries.

Signs and symptoms

A variety of clinical features are associated with Sotos syndrome:

- Newborns are large with respect to length and head circumference; weight is usually average. The rapid growth continues through infancy and into childhood with the child's length/height and head circumference often being above the 97th percentile. The rate of growth appears to decrease in later childhood and adolescence.
- Respiratory and feeding problems (due to hypotonia) may develop in the neonatal period.
- Infants have a round face with prominent forehead and small chin. As the child grows into adolescence and then adulthood the face becomes long and thin, and the chin becomes more prominent.
- Hypotonia is present at birth. This affects the development of fine and gross motor skills, and developmental milestones are usually delayed. Speech is also affected by hypotonia but as the child grows older and the hypotonia resolves or goes away, speech improves.
- Intellect typically is borderline to normal.
- Behavioral problems and emotional immaturity are commonly reported.
- Dental problems such as early eruption of teeth, excessive wear, discoloration, and gingivitis are common.

Diagnosis

Diagnosis of Sotos syndrome is based upon clinical examination, medical history, and x-ray data. There are no laboratory tests that can provide a diagnosis. The clinical criteria that are considered to be diagnostic for Sotos syndrome are excessive growth during the prenatal and postnatal period, advanced bone age, developmental delay, and a characteristic facial appearance. It should be noted that although features suggestive of Sotos syndrome may be present at birth or within 6–12 months after birth, making a diagnosis in infancy is not clear-cut and may take multiple evaluations over several years.

QUESTIONS TO ASK YOUR DOCTOR

- Please describe the progress of Sotos syndrome from the time it first appears in a fetus.
- What specific signs and symptoms are typically associated with Sotos syndrome?
- What do parents need to do to manage a child's health as she or he matures with Sotos syndrome?
- In what respects will a child with Sotos syndrome be able or not be able to live a normal life?

There are many conditions and genetic syndromes that cause excessive growth, consequently, a baby and/or child who has accelerated growth needs to be thoroughly examined by a physician knowledgeable in overgrowth and genetic syndromes. The evaluation includes asking about health problems in the family as well as asking about the growth patterns of the parents and their final height. In some families, growth patterns are different and thus may account for the child's excessive growth. The child will also undergo a complete physical examination. Additional examination of facial appearance, with special attention paid to the shape of the head, width of the face at the level of the eyes, and the appearance of the chin and forehead is necessary as well. Measurement of the head circumference, arm length, leg length, and wing span should be taken. Laboratory testing such as chromosome analysis (karyotype) may be done along with testing for another genetic syndrome called fragile-X. A bone age will also be ordered. Bone age is determined by x-rays of the hand. If the child begins to lose developmental milestones or appears to stop developing, metabolic testing may be done to evaluate for a metabolic condition.

Treatment and management

There is no cure or method for preventing Sotos syndrome. However, the symptoms can be treated and managed. In the majority of cases, the symptoms developed by individuals with Sotos syndrome are treated and managed the same as in individuals in the general population. For example, physical and occupational therapy may help with muscle tone, speech therapy may improve speech, and behavioral assessments may assist with behavioral problems.

Managing the health of a child with Sotos syndrome includes regular measurements of the growth parameters (i.e., height, head circumference and weight); excessive

growth is not treated. Regular eye and dental examinations are also recommended. Medical screening for congenital heart defects and tumors is not routinely recommended, although it has been noted that symptoms should be evaluated sooner rather than later.

Prognosis

With appropriate treatment, management, and encouragement, children with Sotos syndrome can do well. Adults with Sotos syndrome are likely to be within the normal range for height and intellect. Sotos syndrome is not associated with a shortened lifespan.

SPARCA1 spectrin-associated autosomal recessive cerebellar ataxia type1

Definition

Spectrin-associated, autosomal-recessive cerebellar ataxia type1 (SPARCA1) is an inherited neurological disorder. It is characterized by delayed psychomotor development, severe early-onset ataxia (the inability to

KEY TERMS

Ataxia—The inability to control voluntary muscle movement.

Autosomal recessive—A pattern of genetic inheritance in which two abnormal genes are needed to express the trait or disorder.

Beta-III spectrin—A protein that forms the scaffolding (cytoskeleton) of cell membranes in combination with alpha spectrins.

Cerebellum—The part of the brain between the brain stem and the back of the cerebrum that is involved in muscle coordination and maintaining bodily equilibrium.

Lincoln ataxia (SCA5)—Spinocerebellar ataxia type 5; an adult-onset cerebellar ataxia caused by autosomal dominant mutations in the SPTBN2 gene.

Neuronal spectrinopathies—Neurological disorders such as SPARCA1 and SCA5 that are caused by mutations in genes encoding brain spectrins.

Spinocerebellar ataxia, autosomal recessive 14 (SCAR14)—Spectrin-associated autosomal recessive cerebellar ataxia type1 (SPARCA1).

SPTBN2—Spectrin, beta, nonerythrocytic 2; the gene that encodes beta-III spectrin.

coordinate voluntary movement), intellectual disability, abnormalities of eye movement, and atrophy (degeneration) of the cerebellum—the part of the brain that coordinates muscles and maintains equilibrium. SPARCA1 is also known as spinocerebellar ataxia, autosomal recessive 14 (SCAR14).

Description

Ataxia is a large family of disorders of varying degrees of severity, characterized by impaired balance, coordination, and speech. The many different subtypes of inherited ataxias are caused by mutations in a variety of different genes. SPARCA1 is a newly identified type of inherited severe ataxia. In addition to ataxia caused by progressive atrophy of the cerebellum, SPARCA1 is unusual in that it also causes mild-to-moderate global cognitive impairment beginning in childhood. It is related to spinocerebellar ataxia type 5 (SCA5) or "Lincoln ataxia," which was first identified in descendants of relatives of U.S. President Abraham Lincoln. SPARCA1 and SCA5 are both caused by mutations (changes) in a gene called *SPTBN2* that produces a protein in the cerebellum

called beta-III spectrin. However, unlike SPARCA1, Lincoln ataxia is a slowly progressing disorder of cerebellum function that usually does not develop until adulthood and does not involve intellectual impairment. SPARCA1 is inherited in an autosomal recessive pattern, meaning that an affected individual has inherited two copies of a mutated *SPTBN2* gene, one copy from each parent. In contrast, Lincoln ataxia is autosomal dominant, meaning that an affected individual has inherited only one altered copy of the *SPTBN2* gene, along with one normal copy of the gene. Autosomal dominant mutations causing SCA5 were first identified in the *SPTBN2* gene in 2006.

A genetic defect resulting in SPARCA1 was first identified in 2012 by whole-genome sequencing—determining the sequence of all of the DNA of affected individuals and their parents. The researchers also studied the condition in mice lacking beta-III spectrin and showed that the lack of this protein causes changes in the shape of nerve cells in brain areas important for coordinated movement and cognition. Thus, it appears that the complete absence of beta-III spectrin protein in autosomal recessive SPARCA1 causes childhood ataxia and intellectual impairment. These signs are not seen in SCA5, in which some beta-III spectrin is produced by the second normal *SPTBN2* gene. The researchers' data suggest that beta-III spectrin is involved in the development of the cortex of the brain as well as in cerebellar development and function. Furthermore, the early onset of SPARCA1 suggests that beta-III spectrin is important for prenatal cerebellar development.

Beta-III spectrin is only one of many spectrin proteins that are important for brain development and function. Spectrins are a diverse family of proteins that join together to form the scaffolding or cytoskeleton of cell membranes in many different types of cells. A growing number of conditions are being identified as resulting from abnormal spectrin functioning in nerve cells. These are referred to collectively as neuronal spectrinopathies and include SPARCA1, SCA5, and a form of West syndrome.

Genetic profile

More than 100 different genes have been associated with ataxia. Mutations in at least 20 different genes have been identified as causing autosomal recessive cerebellar ataxias, which are often apparent at birth and are accompanied by developmental delays. Nevertheless, about 40% of cases of autosomal recessive cerebellar ataxia are caused by mutations in genes that have not yet been identified.

QUESTIONS TO ASK YOUR DOCTOR

- What type of cerebellar ataxia does my child have?
- Is genetic testing available for cerebellar ataxia?
- What are the chances that we will have another child with the same disorder?
- What treatments are available for my child?
- What is my child's prognosis?

The *SPTBN2* gene (SPecTrin, Beta, Non-erythrocytic 2) that causes SPARCA1 (SCAR14) and SCA5 is located on the long arm (q) of chromosome 11 at 11q13. A single dominant mutation causes SCA5, and recessive mutations in both *SPTBN2* genes cause SPARCA1. The first known SPARCA1-associated mutation was identified in three affected members of a consanguineous (marriage between related individuals) Pakistani family living in the United Kingdom. The same mutation was present in both *SPTBN2* genes of the affected individuals. It was the first recessive mutation to be identified in any brain spectrin protein. The gene mutation introduced a stop codon that caused the beta-III spectrin protein to terminate prematurely. The parents of the affected family members each carried one mutated *SPTBN2* gene and one normal *SPTBN2* gene and had no symptoms of the disorder.

In 2014, researchers reported on an Egyptian family with SPARCA1-affected members who had two mutated *SPTBN2* genes with a five-base-pair deletion that also resulted in a truncated (shortened) beta-III spectrin protein.

Demographics

Ataxia and cerebellum atrophy affect about 1.5 million people worldwide. Autosomal recessive cerebellar ataxias affect about 5 people in 100,000. SPARCA1 is presumed to be very rare since, as of 2015, it had been identified in only two families. Likewise, SCA5 had been described in only three families.

Signs and symptoms

The signs and symptoms of SPARCA1 are the following:

- global developmental delay with severely delayed psychomotor development, including aided walking beginning between the ages of two and seven and a half years

- gait ataxia (uncoordinated walking)
- cognitive and speech delays in the learning-disabled range
- abnormal eye movements

Diagnosis

Diagnosis of SPARCA1 is based on developmental delays, early-onset cerebellar ataxia, brain imaging studies, and genetic analysis. Computed tomography (CT) scans of the brains of the youngest patients showed no abnormalities or only mild underdevelopment of the posterior corpus callosum that connects the two hemispheres of the cerebrum. However, by the age of six, magnetic resonance imaging (MRI) showed cerebellar atrophy that had progressed over time. The parents of affected children, each carrying one mutated *SPTBN2* gene, had normal neurologic exams with no evidence of ataxia.

Treatment and management

There is no specific treatment for inherited cerebellar ataxias. The children who have been identified with SPARCA1 walk with aids and receive special education.

Prognosis

There is no cure for SPARCA1 or other inherited cerebellar ataxias. People with SPARCA1 will require assistance throughout life. Life expectancy is unknown.

Spastic cerebral palsy

Definition

Spastic cerebral palsy (CP) is a disorder in which brain damage results in a movement disability.

Description

Cerebral palsy is a nonprogressive disorder of movement and/or posture caused by a brain abnormality. It is evident before the age of two. There are several types of CP, but spastic CP is the most common—about 60% of all cases. The term "spasticity" refers to increased muscle tone (stiffness), leading to uncontrolled, awkward movements.

Genetic profile

Only about 2% of cases of CP are believed to result from genetic causes. Most cases of CP are associated with risk factors such as low birth weight, premature birth, and lack of oxygen at birth. Multiple births (such as twins or triplets) also have an increased risk. A genetic cause is more likely if these risk factors are not present. If the paralysis and spasticity are symmetrical—that is, if both sides of the body are similarly affected—then the condition is more likely to be genetic in nature. Intellectual disability is usually, but not always, associated with genetic forms. Researchers have not yet found which gene is associated with the disease.

Demographics

CP has an overall incidence of 1 in 250 to 1,000 births. Most forms of CP that are genetic have an autosomal recessive pattern of inheritance. This means that in order for a child to have the disorder, they must inherit one altered copy of the causative gene from each parent. A person who has only one altered copy of the disease gene is called a carrier. Two carriers have a 25% chance of having a child with CP with each pregnancy. As studied in the British Pakistani population, a consanguineous marriage—marriage between relatives—appears to increase the prevalence of a genetic form of spastic CP.

KEY TERMS

Cerebral palsy—Movement disability resulting from nonprogressive brain damage.

Spasticity—Increased muscle tone, or stiffness, which leads to uncontrolled, awkward movements.

Signs and symptoms

CP may not be noticed immediately after birth. Children with CP are slow to meet developmental motor milestones, which are expected ages at which certain mobility skills are achieved. These milestones include reaching for toys, sitting, and walking. People with CP also have abnormal muscle tone (increased in spastic CP), abnormal or uncontrolled movements, and abnormal reflexes. The spasticity may not be present at birth but usually develops during the first two years of life. Many children with spastic CP have normal intelligence, but intellectual disability does occur, especially in inherited forms of the disease. Depending on the severity and extent of the paralysis, some affected individuals can walk (often late and with crutches or walkers), while others with more severe disability cannot walk at all. Seizures are not uncommon in individuals with CP.

Diagnosis

A diagnosis of spastic CP is based on delay in or lack of meeting developmental motor milestones, along with the presence of abnormal muscle tone, movements, and reflexes. Since the exact gene causing some cases of symmetric spastic CP has not yet been identified, molecular testing is not available at this time. Since CP-like symptoms can be found in other genetic conditions, chromosome testing and molecular testing for other suspected conditions may help determine the cause of the CP-like symptoms. Testing may also enable other family members to see if they carry the condition, and allow a fetus to be diagnosed prenatally. Prenatal diagnosis of known genetic conditions can be accomplished using procedures such as chorionic villi sampling, in which cells from the placenta are studied; and amniocentesis, in which skin cells from the fluid surrounding the fetus are studied.

Treatment and management

Treatment of spastic CP is focused on maximizing mobility through physical therapy, and/or providing necessary physical support using devices such as splints, walkers, and wheelchairs. Speech and occupational therapy are sometimes useful as well. Certain types of

QUESTIONS TO ASK YOUR DOCTOR

- What bodily changes are characteristic of a child with spastic cerebral palsy?
- What kind of home care will a child with spastic cerebral palsy require as he or she grows older?
- What physical, mental, and emotional problems is a child with spastic cerebral palsy likely to experience?
- What organizations provide advice and support for parents of a child with spastic cerebral palsy?

surgery of the bone, nerves, tendon, and brain tissue can correct abnormalities, improve mobility, and reduce spasticity. Orthodontic work on the teeth is often indicated in children with CP. Some level of special educational services is usually required.

Prognosis

Spastic CP is not a progressive condition, so living into old age is possible. However, complications such as reduced mobility, mental retardation, feeding difficulties, and respiratory infections can reduce the lifespan. More severe disabilities are associated with greater decreases in life expectancy, but at least half of people with CP live to at least age 35.

Spina bifida

Definition

Spina bifida is a serious birth abnormality termed a neural tube defect, in which the spinal cord is malformed and lacks its usual protective skeletal and soft tissue coverings.

Description

Spina bifida is a lesion that may appear in the midline of the body anywhere from the neck to the buttocks. It is caused by the failure of the vertebrae to form properly in fetal development, leaving the spinal cord in some degree of vulnerability or exposure to the environment.

Illustration showing the three main types of spina bifida.
(Peter Gardiner/Science Source)

Spina bifida occurs in multiple forms of varying exposure of the spinal cord.

Spina bifida occulta

This form of spina bifida usually involves the deformation of a single vertebra in the cervical, lumbar, or sacral regions. The spinal cord and nerves are usually normal with no neurological symptoms. There is typically skin covering the vertebral abnormality, which is indicated visually by a dimple with a tuft of hair. Clinical symptoms are absent in the majority of cases.

Spina bifida cystica

Spina bifida cystica is a term used to describe several severe forms of spina bifida. The spinal cord protrudes outward through an open defect in the vertebrae, forming a cyst-like sac on the outside of the body that is filled with cerebrospinal fluid. When the sac includes the meninges, a protective three-layered membrane that covers the spinal cord, the condition is said to involve a meningocele. When the actual spinal cord or nerve roots are included in the sac, the condition is described as involving a meningocele. This is a more common form of spina bifida cystica. Neurological deficits occur because nervous tissue is integrated in the wall of the sac and disrupt their function. Both types of spina bifida cystica are most common in the lumbar and sacral regions of the spine.

Rachischisis and spina bifida with myeloschisis

The most severe type of spina bifida is caused by the failure of the neural folds to fuse. The entire spinal canal is open, exposing the spinal nerves completely and the spinal cord is only developed into a flattened mass of nervous tissue.

Spina bifida is usually readily apparent at birth because of the malformation of the back and clinical symptoms associated with most forms of the abnormality. There are varying degrees of neurological deficit present that depend on the position and degree of the abnormality. There is usually a loss of sensation to the skin with varying skeletal muscle paralysis in the region below the lesion. Paralysis of the urinary bladder or anal sphincters is also common in these forms of the disease.

Genetic profile

Spina bifida may occur as an isolated defect or associated with other malformations, such as partial absence of the brain. As an isolated abnormality, spina bifida is caused by a combination of genetic factors and environmental influences. The most important factor that causes

neural tube defects such as spina bifida is a maternal folic acid deficiency during early pregnancy. Folic acid levels are dependent on dietary intake; during pregnancy the requirement for folic acid is increased and is difficult to meet with an average contemporary diet. Mothers of children with neural tube defects may have reduced folate levels in their blood, along with a defect in the recycling pathway for digested folic acid. This defect can be caused by a genetic mutation in the enzyme 5,10-methylenetetrahydrofolate reductase (MTHFR). The mutation in the gene for MTHFR causes an unstable enzyme that cannot function properly in the metabolism of folic acid. The mutant allele for unstable MTHFR is very common in many populations. Between 5% and 15% of the population may have both alleles for a mutated form of MTHFR. Research has demonstrated that mothers of infants with neural tube defects are twice as likely to have all mutant alleles of the gene for MTHFR. A folic acid deficiency may be caused by other genetic defects or by dietary deprivation alone. A small percentage of neural tube defects such as spina bifida can be narrowed down to other specific causes, such as the early rupture of the amnion-forming fibrous amniotic bands that disrupt vertebral development. Exposure to some chemicals that produce abnormal fetal development (teratogens) may cause spina bifida. Other causes may include separate single gene mutations, chromosomal abnormalities, environmental insults such as maternal diabetes mellitus, or prenatal exposure to certain anticonvulsant drugs. The recurrence risk varies with each of these specific causes.

Demographics

Spina bifida occurs worldwide but there has been a steady decrease in occurrence rates over the past 50–70 years, most likely due to dietary supplementation with folic acid. Before folic acid fortification, some form of neural tube defect affected approximately 2,500–3,000 births in the United States annually. In 2001, there was a 24% decline in spina bifida in the United States from folic acid fortification of enriched grain products and other folic acid initiatives. The highest prevalence rates, about 1 in 200 pregnancies, have been reported from northern provinces in China. High prevalence rates of approximately 1 in 1,000 pregnancies have also been found in Central and South America. The lowest prevalence rates, fewer than 1 in 2,000 pregnancies, have been found in European countries. Regionally, the highest prevalence in the United States occurs in the Southeast, in approximately 1 in 500 pregnancies. A study performed by the Centers for Disease Control and Prevention (CDC) in North Carolina between 1995 and 1999 demonstrated a 32% decline in the incidence of spina bifida. The decline

KEY TERMS

Allele—One of two or more different variants of the same gene that encode specific and inheritable characteristics that occupy corresponding locations on a pair of chromosomes.

Amnion—The thin, protective sac that suspends the fetus in a protective amniotic fluid.

Anesthesia of the skin—A loss of feeling or sensation in the skin associated with spine-related injury or disorders.

Cerebrospinal fluid—Fluid that bathes and supports the brain and the spinal cord, protecting it from physical impact.

Chiari II anomaly—A structural abnormality of the lower portion of the brain (cerebellum and brain stem) associated with spina bifida; the lower structures of the brain are crowded and may be forced into the foramen magnum, the opening through which the brain and spinal cord are connected.

Hydrocephalus—The excess accumulation of cerebrospinal fluid around the brain that often causes enlargement of the head.

Neural folds and tube—Portions of the developing embryo from which the brain and spinal cord arise.

Vertebral divisions—The human vertebral regions are divided into cervical, thoracic, lumbar, and sacral from the neck to the tailbone.

in incidence was not uniform across the population but was dependent on geographic region, and correlated with maternal sociodemographic characteristics. Populations with higher income and education have undergone the greatest decline in spina bifida and, although the use of multivitamins has played a role in this population, much of the recent decline in neural tube defects in the United States has been a result of the mandatory government fortification program of enriched grain products.

Signs and symptoms

In most cases spina bifida is obvious at birth because of the malformation of the spinal column and associated neurological deficits. The spinal cord may be completely exposed, appearing as a mass on the back covered by the meningeal membranes or skin. Although spina bifida may occur anywhere from the base of the skull to the buttocks, about 75% of cases occur in the lumbar region. When the defect is covered by skin it may include a

dimple or depression, a port wine-colored birthmark, or a bulge with a tuft of hair.

Along with the malformations the neurological deficit is also obvious, often manifesting as a loss of sensation or feeling in the skin. This level of anesthesia of the skin depends on which dermatomes are affected. Dermatomes are patches of skin innervated by specific spinal nerves. The spinal nerves leave the spinal cord to innervate structures in descending order. The higher the lesion of spina bifida is located on the vertebral column, the more spinal nerves may be affected. Skeletal muscle may also be paralyzed in the same fashion, sometimes over the entire pelvic area and lower extremity. Saddle anesthesia is the term used to refer to the entire loss of sensation to the area of the body that touches the saddle during horseback riding. Saddle anesthesia is a symptom often seen when paralysis of urinary bladder and anal sphincters is present. A lack of response to touch, leg movement or resistance to passive-elicited movement, severe flaccidity, and lack of anal reflex (reflex of musculature in response to touch) in an infant are signs that neurological deficits in the lower region are present.

There are other complications that sometimes develop in association with spina bifida. Some infants develop hydrocephaly, an accumulation of excess fluid in the four cavities of the brain. At least one in every seven cases develops symptoms of Chiari II malformation, a condition in which the lower part of the brain is crowded and may be forced into the upper part of the spinal cavity. A lipomeningocele or lipomyelomeningocele may occur in the lumbar or sacral back area. In these conditions a tumor of fatty tissue becomes isolated among the nerves below the spinal cord, which may result in tethering of the spinal cord and complications similar to those with open spina bifida.

Diagnosis

A mother carrying a fetus with spina bifida will not experience any unusual signs or symptoms in early pregnancy. Initial signs and symptoms in the maternal amniotic fluid are often used to discover spina bifida prenatally. During amniocentesis obstetricians may screen for high levels of a protein called alphafetoprotein (AFP). High AFP is a general indicator that the fetus may have a defect. The AFP test is not indicative of spina bifida specifically, but alerts the obstetrician that a detailed ultrasonogram (use of ultrasound) may be necessary. Spina bifida may cause elevated levels of AFP because it is an open fetal defect that allows high levels of the AFP of the fetus to travel into maternal amniotic fluid and smaller amounts to enter maternal blood serum. A prenatal diagnosis of spina bifida may be made with ultrasonographic examination. Malformations may be

QUESTIONS TO ASK YOUR DOCTOR

- What is the probability that more than one child with spina bifida will be born into the same family?
- Is there a prenatal test for spinal bifida and, if so, how reliable is it?
- What types of medical problems is a person with spina bifida likely to encounter as he or she grows older?
- Are there Internet resources from which I can obtain additional information about spina bifida?

detected via ultrasonogram as early as 12–14 weeks of pregnancy. A postnatal diagnosis is usually obvious based on external lesions. In addition to the characteristic malformations, paralysis below the level of the lesion may be part of the diagnosis. In cases in which there are no external indicators the diagnosis may not become evident until neurological abnormalities develop weeks, months, or years following birth.

Treatment and management

Prevention of spina bifida and other neural tube defects is improved with the use of folic acid vitamin supplements for several months prior to and following conception. The CDC recommends an intake of 400 mcg of synthetic folic acid per day for all women of childbearing years to prevent neural tube defects.

Open fetal surgery has been performed for spina bifida during the several months of pregnancy. After direct closure of the spine malformation the fetus is returned to the womb. By preventing chronic intrauterine exposure to mechanical and chemical trauma, prenatal surgery improves neurological function and leads to fewer complications after birth. Fetal surgery is considered experimental and results have been mixed.

After birth, aggressive surgical and medical management have improved the survival and function of infants with spina bifida. Initial surgery on the spinal column defect may be performed in the first days of life, providing protection against injury and infection. Subsequent surgery is often necessary to protect against excessive curvature of the spine. When spina bifida occurs in conjunction with hydrocephaly, surgery is performed to implant a mechanical shunt to decrease the pressure and amount of cerebrospinal fluid in the cavities of the brain. Because of weakness or paralysis below the level of the

spinal defect, most children will require physical therapy, bracing, and other orthopedic assistance to enable them to walk. A variety of approaches including periodic bladder catheterization, surgical diversion of urine, and antibiotics are used to protect urinary function.

Although most individuals with spina bifida have normal intellectual function, learning disabilities or mental impairment may occur. This may result in part from hydrocephaly and/or infections of the nervous system. Children so affected may benefit from early educational intervention, physical therapy, and occupational therapy. Counseling to improve self-image and lessen barriers to socialization becomes important in late childhood and adolescence.

Prognosis

More than 80% of infants born with spina bifida survive with surgical and medical management. Although complications from paralysis, hydrocephaly, Chiari II malformation, and urinary tract deterioration threaten the well-being of survivors, the outlook for normal intellectual function is good.

Spinal and bulbar muscular atrophy

Definition

Spinal and bulbar muscular atrophy (SBMA) is a disorder characterized by degradation of the anterior horn cells of the spinal cord resulting in slow progressive muscle weakness and atrophy. This disorder only affects males. Men diagnosed with SBMA often have breast enlargement (gynecomastia) and testicular atrophy, and may have infertility.

Description

Spinal and bulbar muscular atrophy is also known as Kennedy's disease. The disease was first characterized in 1968. SBMA is caused primarily from degradation of the anterior horn cells of the spinal cord, resulting in proximal weakness and atrophy of voluntary skeletal muscle. Anterior horn cells control the voluntary muscle contractions from large muscle groups such as the arms and legs. For example, if an individual wants to move his/her arm, electrical impulses are sent from the brain to the anterior horn cells to the muscles of the arm, which then stimulate the arm muscles to contract, allowing the arm to move. Degradation is a rapid loss of functional motor neurons. Loss of motor neurons results in progressive symmetrical atrophy of the voluntary muscles. Progressive symmetrical atrophy refers to the loss of function of muscle groups from both sides of the body. For example, both arms and both legs are equally affected by similar degrees of muscle loss and the inability to be controlled and used properly. Progressive loss indicates that muscle loss is not instantaneous; rather, muscle loss occurs consistently over a period of time. These muscle groups include those skeletal muscles that control large muscle groups such as the arms, legs, and torso. The weakness in the legs is generally greater than the weakness in the arms.

Proximal weakness is in contrast to distal weakness, and indicates that muscles such as the arms and the legs are affected rather than the muscles of the hands, feet, fingers, and toes. However, the motor neuron of the brain stem and sensory neurons of the dorsal root ganglia are also affected in SBMA. Motor neurons are the neurons that control large muscle groups (arms, legs, torso) of

which anterior horn cells are a subgroup. Sensory neurons are a distinct class of neurons that control an individual's senses. An example would be pain receptors that cause an involuntary reaction to a stimulus such as when a person accidentally grasps a boiling hot kettle and immediately releases the kettle. Dorsal root ganglia are analogous to a headquarters for neurons, through which essentially all neuronal stimuli are processed.

Genetic profile

SBMA is an X-linked recessive disease, meaning the abnormal gene is found on the X chromosome. Since males only inherit one X chromosome (the other is the Y chromosome) they will always express an X-linked disorder if the abnormal gene is on the X chromosome they receive. Females, on the other hand, inherit two X chromosomes. Even if one X chromosome contains the abnormal gene, the second X chromosome with a normal-functioning gene can usually compensate for the other. Males lack the second X chromosome that may be able to mask the effect of the abnormal gene.

The gene with the mutation that causes the symptoms of SBMA is known as the androgen receptor (*AR*) gene and it maps to the proximal long arm of the X chromosome.

The *AR* gene produces a protein that is a member of the steroid-thyroid hormone receptor family and is involved in transcription regulation. Transcription regulation is the molecular process that controls the "reading" of the genetic DNA information and turns it into RNA, which is the material that generates proteins.

Demographics

Because of the X-linked inheritance pattern of SBMA disease, only males are affected by this disorder. Females are carriers of the disease but do not exhibit symptoms. It is estimated that 1 in 50,000 males are affected with SBMA.

Signs and symptoms

SBMA is suspected clinically in a male with an early-adulthood onset of proximal muscle weakness of the limbs; fasciculations (small local contractions of the musculature that is visible through the skin) of the tongue, lips, or area around the mouth; absence of hyperactive reflexes and spasticity; and often evidence of enlarged breasts and/or small testes with few or no sperm.

Diagnosis

SBMA is primarily an adult-onset disease, with symptoms occurring between the third and fifth decades

KEY TERMS

Anterior horn cells—Subset of motor neurons within the spinal cord.

Atrophy—Wasting-away of normal tissue or an organ due to degeneration of the cells.

Degradation—Loss or diminishing.

Dorsal root ganglia—The subset of neuronal cells controlling impulses in and out of the brain.

Intragenic—Occurring within a single gene.

Motor neurons—Class of neurons that specifically control and stimulate voluntary muscles.

Motor units—Functional connection with a single motor neuron and muscle.

Sensory neurons—Class of neurons that specifically regulate and control external stimuli (e.g., sight, sound).

Transcription—The process by which genetic information on a strand of DNA is used to synthesize a strand of complementary RNA.

Voluntary muscle—A muscle under conscious control, such as arm and leg muscles.

of life. Once symptoms present, the disease is slowly progressive. In addition to neuronal cell loss, breast enlargement (gynecomastia), reduced fertility, and testicular atrophy have also been reported in affected males.

The diagnosis is made by a specific molecular genetic test that measures the number of "CAG trinucleotide repeats" in a particular part of the androgen receptor (*AR*) gene. The alteration of the *AR* gene that causes SBMA is an expansion of a CAG trinucleotide repeat in the first part of the gene. In unaffected individuals, between 11 and 33 copies of the CAG trinucleotide are present. In patients with SBMA, this number rises to over 38. The greater the number of expanded repeats, the earlier the age of onset.

Treatment and management

As the bulbar muscles of the face are affected, eating and swallowing can become difficult. Speech and swallowing therapy are useful for helping individuals with SBMA avoid choking due to weakened facial muscles. Due to the weakening of the respiratory muscles, breathing can also be labored. It is therefore essential for patients to undergo chest physiotherapy (CPT). CPT is a standard set of procedures designed to trigger and aid coughing in patients. Coughing is

QUESTIONS TO ASK YOUR DOCTOR

- At what age is SBMA normally diagnosed, and what are the symptoms that lead to that diagnosis?
- Please explain the bodily changes that occur as a result of SBMA.
- How will SBMA affect the projected lifespan of my son, who has just been diagnosed with the condition?
- What are the chances to have another son affected with SBMA, and what is the chance my daughter(s) is/are a carrier for SBMA?

important as it clears the patient's lungs and throat of moisture and prevents secondary problems, such as pneumonia.

As symptoms progress, patients may require a ventilator to aid breathing.

Individuals affected with SBMA can receive physical therapy to increase strength and maintain stability while walking. As the disease progresses, some individuals require braces and walkers to avoid falling.

Prognosis

The majority of patients with SBMA have a normal lifespan. About 10% of older, severely affected patients with SBMA may die from pneumonia or asphyxiation secondary to weakness of the bulbar muscles.

Spinal muscular atrophy

Definition

Spinal muscular atrophy (SMA) is a disease characterized by degradation of the anterior horn cells of the spinal cord and has similar characteristics to spinal and bulbar muscular atrophy (SBMA). SBMA differs from SMA in its mode of inheritance, the disease-determining gene, the mutational events that trigger disease, and the cellular specificity of the disease pathology.

Description

The anterior horn cells control the voluntary muscle contractions from large muscle groups such as the arms and legs. For example, if an individual wants to move his/her arm, electrical impulses are sent from the brain down the anterior horn cells to the muscles of the arm, which then stimulates the arm muscles to contract, allowing the arm to move. Loss of motor neurons due to degradation results in progressive symmetrical atrophy of the voluntary muscles. Progressive symmetrical atrophy refers to the loss of function of muscle groups from both sides of the body. For example, both arms and both legs are equally affected to similar degrees of muscle loss and the inability to be controlled and used properly. Progressive loss indicates that muscle loss is not instantaneous; rather, muscle loss occurs consistently over a period of time. These muscle groups include skeletal muscles that control large muscle groups such as the

arms, legs, and torso. The weakness in the legs is generally greater than the weakness in the arms.

Spinal muscular atrophy (SMA) arises primarily from degradation of the anterior horn cells of the spinal cord and leads to proximal weakness and atrophy of voluntary skeletal muscle. Proximal weakness affects the limbs positioned closer to the body such as the arms and legs rather than more distant body parts such as the hands, feet, fingers, or toes.

Spinal muscular atrophy only affects the motor neurons of the spinal cord and voluntary muscles of the limb and trunk. Patients do not display sensory loss, heart problems, or intellectual disability. There are numerous secondary complications seen in SMA, including bending of the legs and arms and pneumonia. SMA development initially involves a substantial loss of motor units, followed by a stabilization of the surviving motor units. Motor units refer to an entire motor neuron and the connections within a muscle required for neuronal function.

Clinical subgroups

The childhood form of SMA is subdivided into three main clinical subgroups—type I, II, and III—and depends upon the age of onset and severity. A fourth subgroup, type O, was recently discovered in London.

TYPE I. Type I SMA, or Werdnig-Hoffmann disease, is the acute or severe form characterized by severe muscle atrophy. Guido-Werdig, an Austrian doctor, first identified the disease in 1891. He described two brothers displaying progressive muscle weakness from the age of 10 months, starting in the legs and progressing to the back and arms. The first brother died at the age of three with respiratory problems. The second brother survived to the age of six.

Symptoms emerge in the first three months of life, with the affected children never gaining the ability to sit, stand, or walk. Swallowing and feeding may be difficult and the child may show difficulties with his/her own secretions. There is general weakness in the intercostal and accessory respiratory muscles (the muscles situated between the ribs). The chest may appear concave or sunken in due to diaphragmatic breathing.

TYPE II. Type II SMA was first described in 1964. It is less severe than type I, with clinical symptoms emerging between three and 15 months of age. Most patients can sit but are unable to stand or walk unaided. Feeding and swallowing problems are uncommon in patients with type II SMA but as with patients diagnosed with type I SMA, the intercostal muscles are affected, with diaphragmatic breathing as a main characteristic of children with type II SMA. Most patients will survive beyond the age of four years and, depending upon how their respiratory system is affected, may live through adolescence.

KEY TERMS

Anterior horn cells—Subset of motor neurons within the spinal cord.

Atrophy—Wasting-away of normal tissue or an organ due to degeneration of the cells.

Dorsal root ganglia—The subset of neuronal cells controlling impulses in and out of the brain.

Intragenic—Occurring within a single gene.

Motor neurons—Class of neurons that specifically control and stimulate voluntary muscles.

Motor units—Functional connection with a single motor neuron and muscle.

Sensory neurons—Class of neurons that specifically regulate and control external stimuli (e.g., sight, sound).

Transcription—The process by which genetic information on a strand of DNA is used to synthesize a strand of complementary RNA.

Voluntary muscle—A muscle under conscious control, such as arm and leg muscles.

TYPE III. The chronic form of SMA, type III (Kugelberg-Welander disease) was first described in 1956. The clinical symptoms manifest after the age of four. It produces proximal muscle weakness, predominantly in the lower body. Affected individuals can walk unaided and have a normal lifespan depending upon the extent of respiratory muscle loss.

TYPE O. Clinicians in London have recently identified a fourth form of the childhood disease. The type O form appears to have a fetal onset in that affected individuals display reduced movement within the uterus and are born with severe muscular atrophy with massive motor neuronal cell death. Therefore, these patients have very few functional motor neurons and motor units.

Genetic profile

All forms of childhood SMA are autosomal recessive, which requires both parents to be carriers of the disease to pass it to their offspring. If both parents are carriers, there is a 25% chance of their child being affected. All three forms are caused by a decrease in the production of a protein, termed “survival of motor neuron” (SMN). Two almost identical genes that are located on chromosome 5 encode the SMN protein: *SMN-1* and *SMN-2* (previously referred to as telomeric and centromeric SMN, respectively). Remarkably, only mutations or deletions of *SMN-1* result in disease development.

In most unaffected individuals there are two *SMN-1* and two *SMN-2* genes. A subset of SMA-causing mutations is intragenic to single amino acid substitutions within the *SMN-1* gene. Intragenic mutations are those that occur within an otherwise intact *SMN* gene, but that there is a small and very subtle mutation that is only found within the *SMN* gene. This is in contrast to large genomic deletions that can affect the *SMN* gene and its neighboring genes. The intragenic or small mutations thereby confirm *SMN-1* as the SMA-determining gene.

Demographics

Approximately 1 in 10,000 live births is affected with SMA, which is slightly lower than expected since the carrier frequency is between 1 in 40 and 1 in 50. Since this is a recessive disease, meaning two copies of the abnormal gene must be present for the disease to occur, carriers are unaffected because only one copy of the abnormal gene is not sufficient to cause the disease.

The genomic *SMN* region is remarkably unstable and *de novo* mutations (mutations that are new and not inherited from the parents) are quite frequent, accounting for nearly 2% of all SMA cases. In 90% of patients death occurs before the age of two due to respiratory failure. In North America and Europe, type I SMA accounts for 1 in every 25,000 infant mortalities. SMA is the leading genetic cause of infantile death and is the second most common autosomal recessive disorder behind cystic fibrosis. Carrier frequencies and disease frequencies are similar throughout the world, although slight variations can exist. Asian populations have a slightly reduced carrier frequency, although it is not known why this discrepancy has occurred.

Signs and symptoms

Research shows that in SMA, the reduced *SMN* protein levels result in motor neuronal cell degradation. How and why this occurs is still not known.

Diagnosis

One of the main diagnostic tools is electromyography (EMG). Contraction of voluntary muscle is controlled by electrical impulses originating from the brain. These impulses travel down the motor neurons of the spinal cord to the connecting muscles where it triggers the contraction. The EMG records this electrical impulse and determines whether the electric current is the same as in normal individuals. Metal needles are inserted into the arms and thigh and the electrical impulse is recorded.

In addition, the speed at which the electric impulse passes down the motor neuron can also be used as a diagnostic test. In SMA patients both the nerve conduction velocity (NCV) and the EMG readings are reduced.

QUESTIONS TO ASK YOUR DOCTOR

- How do the four types of spinal muscular atrophy differ from each other?
- What is the genetic basis for this disease? Is it the same for all four forms of the condition?
- What are the most common signs and symptoms of spinal muscular atrophy?
- What are the most serious long-term medical problems associated with this genetic disorder?

The third test is an invasive procedure called a muscle biopsy. This involves a surgeon removing a small section of muscle and testing it for signs of degradation.

Treatment and management

To date there is no treatment for childhood SMA, and treatment focuses on providing comfort from the symptoms associated with the disease.

Prognosis

In type I SMA, eating and swallowing can become difficult as the muscles of the face are affected. Due to the degradation of the respiratory muscles breathing can also be labored. It is therefore essential for patients to undergo chest physiotherapy (CPT). CPT is a standard set of procedures designed to trigger and aid coughing in patients. Coughing is important as it clears the patient's lungs and throat of moisture and prevents secondary problems such as pneumonia.

As symptoms progress patients may require a ventilator to aid breathing. There are two main forms of ventilation systems. Negative pressure ventilation can be achieved by placing the patient in a Port-A-Lung. This machine ensures that the air pressure around the patient is lower than the air pressure within the patient's lungs, enabling easier breathing. The pressure can be raised or lowered if the patient's ventilation rate increases or decreases.

The second method is called biphasic positive airway pressure (Bi-Pap). This procedure involves the insertion of a small tube down the nose and into the patient's lungs, through which oxygen is pumped into the lungs and carbon dioxide is removed. This system allows maximum inspiration and expiration levels to be reached.

Of all the forms of childhood SMA, type II is the most diverse. It is therefore hard to tell when muscle weakness will occur and how severe the disease will be. With the aid

of leg braces and walking devices some children may gain the ability to stand. Unlike type I SMA, not all children with type II are affected by respiratory weakness. The main cause of death in patients with type II is respiratory failure resulting from a respiratory infection. It is therefore important to ensure that mucus does not build up in a patient's respiratory tract as this could aid viral and bacterial infections.

Spindle transfer technique

Definitions

The spindle transfer technique, also known as maternal spindle transfer or MST, is one technique employed in mitochondrial replacement therapy (MRT), which is the only approach known to prevent a mitochondrial disease in human offspring as of 2021. Given the lack of treatments for mitochondrial diseases and the limitations of prenatal diagnosis, researchers have focused on preventing the transmission of mitochondrial diseases through germline gene replacement therapy. MST is used during in vitro fertilization (IVF) to replace mitochondria with harmful mutations within a female oocyte (a cell that develops into an ovum by meiosis). The healthy

replacement mitochondria are obtained from a donated oocyte. Because children born as a result of MST and IVF have genetic material derived from two women and one man, they have been referred to in the popular press as three-parent babies.

The term *spindle* in the context of spindle transfer refers to a microscopic network of microtubules (sometimes called spindle fibers) that forms during cell division to pull chromosomes to the poles of the cell during the phase of cell division called metaphase.

Description

Mitochondrial diseases

To understand the significance of spindle transfer and other forms of mitochondrial replacement therapy (MRT), some background information is helpful. Mitochondrial diseases are a group of metabolic disorders in which defective mitochondria within the affected person's cells fail to produce enough energy to meet the body's needs. Mitochondria are microscopic organelles found within all cells of the human body except red blood cells. Sometimes called the powerhouses of the cell, mitochondria convert energy derived from food into adenosine triphosphate (ATP), an organic molecule necessary for most cell functions. But because mitochondria perform a wide range of functions within different body tissues and organs, the symptoms of mitochondrial diseases vary widely, ranging from muscular weakness, loss of balance, nausea, vomiting, developmental delays, and dementia, to pain, kidney or liver failure, vision loss, and difficulty breathing. The website of the United Mitochondrial Disease Foundation (UMDF) contains detailed descriptions of 43 different mitochondrial diseases, but researchers estimate that there are at least several hundred disorders in this category.

Most mitochondrial diseases are genetic disorders. They may be caused either by mutations in the nuclear DNA in the cell or by mutations in the mitochondrial DNA (abbreviated as mtDNA). Most mitochondrial function is encoded by the DNA in the cell nucleus, which in humans is inherited from both parents. In contrast, mtDNA is inherited only from the mother; it contains only 37 genes and encodes 13 proteins. Another difference is that while there are only two copies of DNA in a human cell nucleus, each mitochondrion contains between 2 and 10 copies of mtDNA.

As there are about 500 mitochondria in an average human cell (although liver and muscle cells may contain thousands), the difference in the number of DNA copies means that mutations occur at a much higher rate in mtDNA than in nuclear DNA. When mitochondria multiply during the normal process of cell division, they can accumulate random mutations, a condition called

KEY TERMS

Adenosine triphosphate (ATP)—An organic molecule found in all living organisms, involved in energy production for metabolic processes and RNA synthesis.

Cytoplasm—All of the material within a cell enclosed by the cell membrane, excluding the nucleus. The cytoplasm includes cytosol, organelles (including mitochondria), and various inclusions.

Diploid—Referring to a cell or nucleus that contains two copies of genetic material, or a complete set of chromosomes.

Gamete—A sex cell (sperm or ovum) containing the haploid number of chromosomes, and capable of fusing with a gamete of the opposite sex to form a zygote.

Genome—The total amount of genetic information within an organism's chromosomes, including its genes and DNA sequences.

Germline—The population of a complex organism's cells that pass on genetic information to offspring. Germline cells include eggs, sperm, and fertilized eggs.

Haploid—Referring to cells that have only one chromosome of each type and therefore have only one complete set of genes.

Heteroplasmy—The presence of two or more sources of mitochondrial DNA within a cell, person, or mitochondrion. It is an important factor in determining the severity of a mitochondrial disease.

In vitro fertilization (IVF)—A form of assisted reproduction technology in which a human ovum (egg) is combined with sperm outside the body in a laboratory container ("in vitro" means "in a glass").

Leigh syndrome—A rare genetic disease associated with mutations in either mitochondrial DNA or nuclear DNA, and characterized by degeneration of the central nervous system. It is named for Archibald Denis Leigh, a British psychiatrist who first described the syndrome in 1951.

Meiosis (pronounced my-OH-sis)—The process of cell division during the production of ova and sperm, in which the material in the chromosomes undergoes recombination (first-stage meiosis), and the chromosomes are reduced to a single set of

23 instead of the normal number of 23 pairs (second-stage meiosis)

Metaphase—A stage in the cycle of cell division in which the cell's genetic material condenses into chromosomes, which become visible and line up in the center of the dividing cell.

Mitochondria (singular, mitochondrion)—Organelles in the cytoplasm of cells that contain genetic material and enzymes responsible for converting food to usable energy.

Mitochondrial replacement therapy (MRT)—A technique to prevent or treat certain genetic diseases by replacing the mitochondria in one or more cells. It is also called mitochondrial donation.

Oocyte (pronounced OH-eh-site)—A diploid cell in females from which an egg or ovum develops by meiosis.

Organelle—A specialized structure found within a cell that performs a specific function or carries out a specific life process. Mitochondria are organelles.

Polar body—Either of two small cells produced during the two meiotic divisions in the production of an oocyte. Polar bodies contain only small amounts of cytoplasm and eventually disintegrate.

Pronuclear transfer—A mitochondrial replacement technique in which the mother's egg is first fertilized by the father's sperm; then the two pronuclei are inserted into a donor egg that has been fertilized and has had its own nucleus removed.

Pronucleus (plural, pronuclei)—The nucleus of a sperm or egg cell during the process of fertilization.

Spindle apparatus—A network of microtubules (also known as spindle fibers) that forms during cell division to pull chromosomes during metaphase to the poles of the cell. The microtubules are formed from a protein called tubulin.

Three-parent baby—A term used in the mass media to describe a baby produced from the genetic material of one man and two women through the use of mitochondrial replacement technologies and three-person in vitro fertilization (IVF). It is not a scientific term.

Zygote—A fertilized egg cell that results from the union of two gametes, an egg and a sperm.

heteroplasmy. In some people, only a few mitochondria are affected by these mutations. In others, however, the number of mutant mitochondria increases over time until the mutant organelles dominate the pool of mtDNA. When this threshold is reached, typically in adolescence or early adult life, the person will begin to show symptoms of a mitochondrial disease. About 0.5% of the population carries mtDNA mutations, and about 1 person in every 5,000 (0.02%) is at risk of developing a mitochondrial disease.

In vitro fertilization

Spindle transfer or MST is a recent specialized form of in vitro fertilization, or IVF, which has helped couples with fertility difficulties have children since 1978. About 5 million children around the world have been born through IVF as of 2021. The basic IVF technique involves the administration of hormone therapy to the intended mother to stimulate the release of multiple eggs into the uterus. The eggs are retrieved, selected for health and maturity, and either mixed with sperm or fertilized by the injection of a single sperm into an egg.

The resultant embryos are allowed to mature for a short period of time and then subjected to genetic testing to screen for genetic disorders, abnormal chromosomes, or (as of 2014) defective mitochondrial DNA. The embryos that pass screening are returned to the mother's uterus, where it is hoped that at least one will implant and produce a successful pregnancy.

Spindle transfer technique

If the mother's eggs indicate the presence of mutant mtDNA, an oocyte is removed from the mother. When it reaches the metaphase stage of cell division, the spindle-chromosome complex is removed from the intended mother's oocyte, which is then discarded. The spindle complex is then transferred to a donated oocyte that has had its nuclear DNA removed. The result is a mature egg that contains a selection of the mother's haploid DNA along with healthy mitochondria from the donor. The egg is then fertilized with the father's sperm.

After fertilization, the embryo is allowed to grow until it forms a blastocyst, which is an early pre-implantation stage of the embryo consisting of a hollow sphere of 16 to 40 cells. The blastocyst can then be investigated with preimplantation genetic testing for the presence of mtDNA mutations. If no mutations are found, the blastocyst can be implanted in the intended mother's uterus.

The spindle transfer technique has been performed only rarely since its first use in 2014, as the number of births among women at risk of transmitting diseases

caused by defective mtDNA is estimated to be quite small—about 150 per year in the United Kingdom and 800 per year in the United States.

Legal and regulatory status of spindle transfer

As of 2021, spindle transfer or MST has been approved in the United Kingdom, but is only permitted within clinics approved by the country's Human Fertilization and Embryology Authority (HFEA), and only for patients approved by the HFEA. These approved patients must sign an informed consent form stating that they understand that the risks and benefits of the procedure are not yet well understood. Another country that permits clinical trials of the spindle transfer technique is Greece, where a baby boy was born in April 2019 following use of the technique.

The spindle transfer technique has not been approved by the U.S. Food and Drug Authority (FDA) for use in the United States as of 2021. The agency states that its "jurisdiction includes human cells used in therapy involving the transfer of genetic material by means other than the union of gamete nuclei." In 2014, the FDA convened a meeting of an advisory committee "to discuss oocyte modification in assisted reproduction for the prevention of mitochondrial disease or treatment of infertility."

The meeting was followed in 2015 by a request to the Institute of Medicine (IOM; now called the National Academy of Medicine or NAM) to produce a report on the social and ethical issues involved in mitochondrial replacement therapy. The IOM's report concluded that the spindle transfer technique and other forms of MRT are ethically permissible, provided two conditions are met: 1) treatment should be limited to women at risk of transmitting a severe mitochondrial disease, and 2) research should be limited, at least initially, to male embryos, because female embryos produced by MRT would result in heritable genetic modifications. Paternal mtDNA is not transmitted to offspring, and thus changes made to mtDNA in the male germline are not heritable. The FDA posted its most recent statement on MRT on March 16, 2018.

Because of the FDA's refusal to allow the use of the spindle transfer technique within the United States, the sole American child born to date as a result of MST was delivered in a Mexican hospital in 2016. The baby boy's mother has Leigh syndrome, a rare neurological disorder caused by a mutation in her mtDNA. The physician, John Zhang, runs the New Hope Fertility Center in New York City. Other American women interested in the spindle transfer technique to prevent mitochondrial disease in their offspring must travel to foreign clinics as of 2021. Dr. Zhang has offered the technique in such clinics at a

QUESTIONS TO ASK YOUR DOCTOR

- What is your opinion of the spindle transfer technique?
- Do you think there are limits to the types of assisted reproductive technology that should be allowed?
- What do you consider the most significant risks of mitochondrial replacement therapy?
- Have you ever treated a patient at high risk of bearing a child with a mitochondrial disease? If so, what advice did you offer?

price of \$80,000 to \$100,000 per patient, which prices spindle transfer beyond the reach of most patients.

Limitations

The most important limitation of the spindle transfer technique is that its long-term risks and benefits are unknown as of 2021 because so few children have been born as a result of its use. In the case of the child born in Mexico, the parents of the child have refused to allow ongoing testing of the child's mtDNA, which means that the success of the first human spindle transfer cannot be fully evaluated.

Alternatives

There are several alternatives to spindle transfer to prevent the presence of mutant mtDNA in an embryo. The oldest, in which the doctor or researcher took cytoplasm that included proteins, mRNA, mitochondria, and other organelles from the donor's egg and injected it into the intended mother's egg, is no longer used as of 2021 because several children born as a result of the process were found to have developmental disorders.

The other MRT techniques that have been used are pronuclear transfer (PNT) and polar body transfer (PBT). In pronuclear transfer, the oocyte from the intended mother and the oocyte from the donor are both fertilized with sperm from the same person. The male and female pronuclei (the nucleus of an ovum or sperm before these have united to form the definitive nucleus of an impregnated ovum) are removed from each fertilized egg prior to their fusing, and the pronuclei from the recipient's fertilized egg are inserted into the fertilized egg from the donor.

In polar body transfer, a polar body, which is a small cell with very little cytoplasm created when an oocyte

divides, is taken from the intended mother and used in its entirety instead of using material extracted from the normal egg. The advantage of PBT is that there is a greatly reduced chance of transmitting mitochondria from the intended mother, because polar bodies contain very few mitochondria.

Research

There are no clinical trials of the spindle transfer technique registered with the NIH as of mid-2021—or of any other form of mitochondrial replacement therapy.

Rebecca J. Frey, PhD

Spinocerebellar ataxia

Definition

The spinocerebellar ataxias (SCAs) are a group of inherited conditions that affect the brain and spinal cord and cause progressive difficulty with coordination. Some types of SCA also involve impairment of speech and eye movement.

Description

The SCAs are named for the parts of the nervous system that are affected in this type of condition. *Spino* refers to the spinal cord, and *cerebellar* refers to the cerebellum, the area of the brain that controls coordination. People with SCA often demonstrate smaller and atrophied cerebellums. Symptoms of SCA usually begin in the 30s or 40s but onset from childhood through the 70s has been reported.

At least 60 different types of SCA have been described and are given a designated number as a new case is documented. Each SCA type is caused by mutations in a different gene. Spinocerebellar ataxia has also been called olivopontocerebellar atrophy, Marie’s ataxia, and cerebellar degeneration. SCA3 is sometimes called Machado-Joseph disease, named after two of the first families described with this condition. All affected people in a family have the same type of SCA mutation.

Genetic profile

Although each of the SCAs is caused by mutations in different genes, the types of mutations are the same in all of the genes that have been found. In humans, all genes come in pairs; one copy of a pair comes from a person’s mother and the other one comes from the father. Genes are made up of deoxyribonucleic acid (DNA), composed of the chemical bases cytosine, thymine, guanine, and adenosine, which are represented by the letters C, T, G, and A. This is the DNA alphabet. The bases are usually put together in three-letter combinations called codons. The arrangement of the codons is what give the gene its meaning.

In each of the genes that cause SCA, there is a section of the gene where a three-base DNA codon is repeated a certain number of times. In most of the types of SCA the codon that is repeated is CAG. In people who have SCA this DNA segment is repeated too many times, making this section of the gene too big. This is called a trinucleotide repeat expansion. Other types of SCA are caused by other codon repeats; for example, in SCA8, the DNA codon that is repeated is CTG. In SCA10, the repeated DNA is five DNA bases long and

is ATTCT. This is called a pentanucleotide expansion. The actual number of DNA repeats that is normal or that causes SCA is different in each type of SCA.

In each type of SCA there is a certain range or number of repeats that still fall within the normal range. People who have repeat numbers in the normal range will not develop SCA and cannot pass it to their children. There are also a certain number of repeats that cause SCA that fall within the affected range of nucleotide repeats. People who have repeat numbers in the affected range will go on to develop SCA sometime in their lifetime if they live long enough and potentially pass SCA onto their children. Between the normal and affected ranges there is a gray range. People who have repeat numbers in the gray range may or may not develop SCA in their lifetime and why some people with numbers in the gray range develop SCA and others do not is not known. People with repeat numbers in the gray range can also pass SCA onto their children.

In general the more repeats in the affected range that someone has, the earlier the age of onset of symptoms and the more severe the symptoms will be. However, this is a generalized rule and it is not possible to look at a person's repeat number and predict at what age they will begin to have symptoms or how their condition will progress.

Sometimes when a person with trinucleotide repeat expansion in SCA genes has children, the DNA expansion grows larger during the passing on of genes. This is called anticipation and can result in an even earlier age of onset in children than in their affected parent. Anticipation does not occur in all types of SCA, but significant anticipation can occur in other types; for example, it is not unusual for a child with SCA7 to be affected before their parent or even grandparent begins to show symptoms. In most types of SCA anticipation happens more often when SCA is inherited from the father. However, in SCA8 the opposite is true; anticipation happens more often when a mother passes SCA8 to her children. Occasionally repeat sizes stay the same or even get smaller when they are passed to a person's children.

The SCAs are passed on by autosomal dominant inheritance. This means that males and females are equally likely to be affected by the disorder. It also means that only one gene in the pair needs to have the mutation in order for a person to become affected. Since a person only passes one copy of each gene on to their children, there is a 50% chance that a person who has SCA will pass it on to each of his/her children. A person who has repeat numbers in the gray range also has a 50% chance of passing the gene onto each of his/her children. However, whether or not his/her children will develop SCA

depends on the number of their repeats. A person who has repeat numbers in the normal range cannot pass SCA onto his/her children.

Usually a person with SCA has a long family history of the condition. Sometimes a person with SCA appears to be the only one affected in the family and this can be due to a couple of reasons. First, it is possible that one of the parents is or was affected but died before beginning to show symptoms. Second, the parent may have a mutation in the gray range and was not affected, but the mutation expanded into the affected range when it was passed on to the child. Third, the family members may also have SCA but have been misdiagnosed with another condition or are having symptoms, but have no definitive diagnosis. Lastly, a person can have a new mutation for SCA. New mutations are changes in the gene that happen for the first time in an affected person. Although a person with a new mutation may not have other affected family members, they still have a 50% chance of passing it on to his/her children.

Demographics

SCA has been found in people from all over the world. Some of the types of SCA are more common in certain areas and ethnic groups; the most commonly documented autosomal dominant SCA types are SCA 1, 2, 3, 6, 7, and 8. SCA1 accounts for at least 25% of SCA cases in South Africa and Italy. SCA2 accounts for 25% of SCA cases in Singapore, India, and Italy. SCA3 appears to be the most common type and was first described in families from Portugal and accounts for almost 100% of SCA cases in Brazil. SCA3 also accounts for the majority of SCA cases in Portugal, the Netherlands, Germany, China, Singapore, and a significant proportion in Japan. SCA6 accounts for a significant proportion of SCA cases in the Netherlands, Germany, and Japan. In the United States, SCA2, SCA3, and SCA6 account for the majority of documented cases; these three types also account for 51% of worldwide cases. SCA1, SCA7, and SCA8 each account for less than 10% of SCA cases worldwide.

SCA types 4, 5, and 10 through 26 are rare and have each only been described in a few families. The first family described with SCA5 may have been distantly related to President Abraham Lincoln and was first called Lincoln ataxia. SCA10 has only been described in Mexican families, SCA13 and 25 have each only been described in single French families, SCA14 and 16 have each only been described in single families from Japan, and SCA19 and 23 have each only been described in single Dutch families.

KEY TERMS

Anticipation—Increased severity and onset of disease in successive generations.

Ataxia—A deficiency of muscular coordination, especially affecting voluntary movements such as grasping or walking.

Calcification—The accumulation of calcium deposits.

Trinucleotide repeat expansion—A sequence of three nucleotides that is repeated too many times in a gene sequence.

Signs and symptoms

Although different genes cause each of the SCAs, they all have similar symptoms. All people with SCA have ataxia or a lack of muscle coordination. Walking is affected and eventually the coordination of the arms and hands, speech, and swallowing are also affected. One of the first symptoms of SCA is often difficulties with walking and balance. The muscles that control speech and swallowing are affected by the onset of SCA; this results in dysarthria, or slurred speech, and difficulties with eating. Choking while eating can become a significant problem and can lead to a decrease in the number of calories a person can take in.

As the condition manifests, walking becomes more difficult and it is necessary to use a cane, walker, and often a wheelchair. Because of the uncoordinated walking that develops it is common for people with SCA to be mistaken for being intoxicated. Carrying around a note from their doctor explaining their medical condition can often be helpful in these cases.

Some of the SCA types can also have other symptoms, although not all of these are seen in every person with that particular type. SCA2 may have slower eye movements that do not usually interfere with a person's sight. People with SCA1 and 3 may develop problems with the peripheral nerves, which carry information to and from the spinal cord. This can lead to decreased sensation and weakness in the hands and feet. In SCA3, people may also have twitching in the face and tongue and bulging eyes. SCA4 may cause a loss of sensation, but affected individuals often have a normal lifespan. SCA5 often has an adult onset and is slowly progressive, not affecting the lifespan. SCA6 often has a later onset, progresses very slowly, and does not shorten the lifespan. SCA7 involves progressive vision loss that eventually leads to blindness. SCA8 may cause sensory loss but

people have a normal lifespan. SCA10 may cause affected individuals to develop seizures. SCA11 is a relatively mild type and does not affect the lifespan for the affected person. Cases of SCA12 often develop a tremor as the first noticeable symptom and the individuals may eventually develop dementia. SCA13 may cause individuals to be shorter than average and have mild mental retardation. SCA14 may have an early onset, between 12 and 42 years of age, with an average of 28 years of age. SCA15 and 22 may be slow to progress, with SCA22 sometimes being early onset. SCA16 may involve tremors, SCA17 may involve mental deterioration, and SCA19 may involve both. SCA20 may result in calcification of some brain areas that shows up on brain imaging tests. SCA21 can be early onset, but involve only mild cognitive impairment. SCA23 is late onset and may involve sensory loss. SCA25 may also cause sensory loss. SCA26 may involve irregular eye movements.

Diagnosis

Genetic forms of ataxia must be distinguished from nongenetic causes of ataxia that may have their own, individual treatment. Nongenetic causes of ataxia are not types of SCA and can include alcoholism, vitamin deficiencies, multiple sclerosis, vascular disease, and some cancers. Family history, physical examination, and brain imaging diagnose the genetic forms of ataxia, such as SCA.

An initial workup of people who are having symptoms of ataxia will include questions about a person's medical history and a physical examination. Magnetic resonance imaging (MRI) of the brain in people with SCA will usually show degeneration or atrophy of the cerebellum and may be helpful in suggesting a diagnosis of SCA. A thorough family history should be taken to determine if others in the family have similar symptoms and the inheritance pattern in the family.

Since there is so much overlap between symptoms in the different types of SCA it is not usually possible to tell the different types apart based on clinical symptoms. The only way to definitively diagnose SCA and determine a specific subtype is by genetic testing. DNA in the blood cells is examined, and the number of CAG repeats in each of the SCA genes is counted. Clinical testing is available to detect the mutations that cause SCA types with known gene mutations. These tests may be offered as two sequential groups based on population frequency. Testing is often first performed for the more common ataxias, SCA1 through SCA7. Testing for the less common hereditary ataxias are often individualized as appropriate. Factors that may indicate the need for testing for less common SCA types can include ethnic background (SCA10 in the Mexican population), or specific symptoms, such as the presence of a tremor (SCA12). In these

cases, testing can be performed for a single disease. If the outcome is negative for the SCA type tested for, it does not mean that a person does not have SCA, it could mean that he/she has a type of SCA for which genetic testing is not yet available.

It is possible to test someone who is at risk for developing SCA before they are showing symptoms to see whether he/she inherited an expanded trinucleotide repeat. This is called predictive testing. Predictive testing cannot determine the age of onset that someone will begin to have symptoms or the course of the disease. The decision to undergo this testing is a very personal decision and some people choose to have testing so that they can make decisions about having children, about their future education, career, or finances. Protocols for predictive testing have been developed and only certain centers perform this testing. Most centers require that the diagnosis of SCA be confirmed by genetic testing in another family member.

A team of specialists will see a person who is interested in testing over the course of a few visits. Often they will meet a neurologist who will perform a neurological examination to see if they may be showing early signs of the condition. If a person is having symptoms, testing may be performed to confirm the diagnosis, and the person will also meet with a genetic counselor to talk about SCA, how it is inherited, and what testing can and cannot determine. He/she will also explore reasons for testing and what impact the results may have on his/her life, family, job, and insurance. Most centers also require a person going through predictive testing to meet a few times with a psychologist. The purpose of these visits is to make sure that the person has thought through the decision to be tested and is prepared to deal with whatever the results may be.

If a child is having symptoms, it is appropriate to perform testing to confirm the cause of his/her symptoms. However, testing will not be performed on children who are at risk for developing SCA, but are not having symptoms. Children can make their own choice whether to know this information when they are old enough to make a mature decision. Testing a child who does not have symptoms could lead to possible problems with future relationships, education, career, and insurance.

Testing a pregnant woman to determine whether an unborn child is affected is possible if genetic testing in a family has identified a certain type of SCA. This can be done between 10 and 12 weeks gestation by a procedure called chorionic villus sampling (CVS) that involves removing a tiny piece of the placenta and examining the cells. It can also be done by amniocentesis after 16 weeks gestation by removing a small amount of the amniotic fluid surrounding the fetus and analyzing the cells in the fluid. Each of these procedures has a small risk of

QUESTIONS TO ASK YOUR DOCTOR

- A distant relative was once diagnosed with spinocerebellar ataxia. Is there any way of knowing if I am at risk for this condition?
- What are the most common symptoms associated with this disorder?
- At what age does spinocerebellar ataxia first manifest?
- What is the prognosis for spinocerebellar ataxia once it has been diagnosed?

miscarriage associated with it. Continuing a pregnancy that is affected is like performing predictive testing on a child. Therefore, couples interested in these options should have genetic counseling to carefully explore all of the benefits and limitations of these procedures.

There is also another procedure, called preimplantation diagnosis, that allows a couple to have a child that is unaffected with the genetic condition in their family through the application of in vitro fertilization.

Treatment and management

Although there is a lot of ongoing research to learn more about SCA and develop treatments, no cure currently exists for the SCAs. Although vitamin supplements are not a cure or treatment for SCA, they may be recommended if a person is taking in fewer calories because of feeding difficulties. Different types of therapy might be useful to help people maintain as independent a lifestyle as possible. An occupational therapist may be able to suggest adaptive devices to make the activities of daily living easier. Canes, walkers, and wheelchairs are often useful. A speech therapist may recommend devices that may make communication easier as speech progressively becomes affected. As swallowing becomes more difficult, a special swallow evaluation may lead to better strategies for eating and to help lessen the risk of choking.

Genetic counseling helps people and their families make decisions about their medical care, genetic testing, and having children. It can also help people to deal with the medical and emotional issues that arise when there is a genetic condition diagnosed in the family.

Prognosis

Most people with the SCAs do have progression of their symptoms that leads to full-time use of a wheelchair. The duration of the disease after the onset of symptoms is

about 10–30 years but can vary depending in part on the number of trinucleotide repeats and age of onset. In general, people with a larger number of repeats have an earlier age of onset and more severe symptoms. Choking can be a major hazard because if food gets into the lungs, life-threatening pneumonia can result. As the condition progresses, it can become difficult for people to cough and clear secretions. Most people die from respiratory failure or pulmonary complications.

Spinocerebellar ataxia 3

Definition

Spinocerebellar ataxia Type 3 (SCA3) is a rare hereditary disorder affecting the central nervous system, especially the areas responsible for movement coordination of limbs, facial muscles, and eyes. The disease involves the slow and progressive degeneration of areas

of the brain, including the cerebellar, extrapyramidal, pyramidal, and motor areas. Although SCA3 leads to paralysis of different levels of severity, intellectual functions usually remain normal. Other names for SCA3 are Portuguese-Azorean disease, Machado-Joseph disease, and Azorean disease.

Description

Many of the reported cases have been found in the direct descendants of William Machado, an Azorean native who immigrated to the New England region of the United States, and Atone Joseph, a Portuguese sailor from the island of Flores who came to California in 1845. SCA3 was first described and documented as Machado-Joseph disease in 1972 among the descendants of Portuguese-Azorean immigrants to the United States, including the family of William Machado. In 1976, investigators went to the Azores Archipelago to study an existing neurodegenerative disease in the islands of Flores and São Miguel. In a group of 15 families, they found 40 people with neurological disorders with a variety of symptoms among the affected individuals, suggesting that SCA3 can vary in the degree of neurological degeneration and movement impairment among the affected individuals.

Another research team in 1976 reported an inherited neurological disorder of the motor system in Portuguese families, which they named Joseph disease. During the same year, the two groups of scientists both published independent evidence suggesting that the same disease was the primary cause for the symptoms observed. When additional reports from other countries and ethnic groups were associated with the same inherited disorder, it was thought that Portuguese-Azorean sailors had been the probable disseminators of SCA3 during the sixteenth-century period of Portuguese colonial explorations and commerce.

Genetic profile

SCA3 is inherited as an autosomal dominant trait. This means that only one parent has to pass on the gene mutation in order for the child to be affected with the disease.

Each gene in the human body is made up of units called nucleotides, abbreviated C (cytosine), A (adenine), T (thymine), and G (guanine). A sequence of three nucleotides is called a codon. SCA3 is caused by a genetic mutation that results in the overduplication of a repeated CAG codon in the gene sequence. This form of mutation is called a trinucleotide repeat expansion. The location of the mutant gene in SCA3 is *14q32*, on the long arm of chromosome 14. This gene normally encodes

the formation of a cellular protein called ataxin-3 (ATXN3). In the general population, there are between 13 and 36 repeats of the CAG codon, but in those individuals with SCA3 there may be between 61 and 84 repeats. The increased number of repetitions causes the gene to encode an abnormal ATXN3 protein product that is believed to cause cell death in the brain and spinal cord.

In successive generations the number of the repetitions may increase and cause the disease to develop at earlier ages and with more severity, a phenomenon known as genetic anticipation. In addition, there appears to be a strong relationship between the number of repetitions and the age of onset of SCA3: the more repetitions, the sooner the disease presents and the more serious the symptoms are. Also, if the individual is homozygous for the mutated gene, meaning he or she inherits the gene from both parents, SCA3 is more severe, and onset can be as early as 16 years old.

Demographics

Due to its origins, SCA3 is primarily found in people of Portuguese ancestry, particularly people from the Azores islands. In the Azores islands, the incidence of SCA3 is approximately 1 in every 4,000 people, while among those of Azorean descent it is 1 in every 6,000. SCA3 has also been identified in other ethnic groups including Japanese, Brazilians, Chinese, Indians, Israelis, and Australian aborigines.

Signs and symptoms

The symptoms of SCA3 result from the loss of brain cells, leading to the impairment of neurological connections in the brain and spinal cord. This degradation of the central nervous system is caused by gene mutation, which produces an abnormal form of a protein. The first symptoms usually appear in early adolescence. Dystonia (gait ataxia) is usually the initial symptoms in children. Gait ataxia is characterized by unstable walking and standing, and can slowly progress with the appearance of some of the other symptoms, such as hand dysmetria, involuntary eye movements, loss of hand and superior limb coordination, and facial dystonia. Another characteristic of SCA3 is clinical anticipation, which means that the disease presents earlier and with more severity in subsequent generations. Among families, some members may show a predominance of muscle tone disorders, loss of coordination, have bulging eyes, or some may be free of symptoms during their entire life. In the late stages of SCA3, some people may experience delirium or dementia.

Depending on the affected brain area, SCA3 is classified as type I, extrapyramidal insufficiency; type II, cerebellar, pyramidal, and extrapyramidal insufficiency; and

KEY TERMS

Ataxia—A deficiency in muscular coordination, especially voluntary movements, such as grasping or walking.

Autosomal chromosomes—Relating to any chromosome besides the X and Y sex chromosomes. Human cells contain 22 pairs of autosomal chromosomes and one pair of sex chromosomes.

Cerebellum—The part of the brain that is responsible for the control of walking, balance, and coordination.

Codon—A sequence of three nucleotides that code for specific amino acids.

Dysarthria—Slurred speech.

Dystonia—Painful involuntary muscle cramps or spasms.

Extrapyramidal—Refers to brain structures located outside the pyramidal tracts of the central nervous system.

Genetic anticipation—The tendency for an inherited disease to become more severe in successive generations.

Genotype—The genetic makeup of an organism.

Homozygous—Having two identical copies (alleles) of a gene.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease. Some mutations can be transmitted to offspring.

Nucleotide—The single building block of DNA and RNA.

Penetrance—The degree to which individuals possessing particular genetic mutations express the trait that this mutation causes. One hundred percent penetrance is expected for truly dominant traits.

Phenotype—The physical expression of an individual's genotype.

Spasticity—Increased muscle tone or stiffness that leads to uncontrolled, awkward movements.

Trinucleotide repeat expansion—The addition of extra nucleotides during DNA replication of highly repetitive genetic sequences. This can lead to mutations in genes coded in the affected region of the genome.

type III, cerebellar insufficiency. Extrapyramidal tracts are networks of uncrossed motor nerve fibers that function as relays between the motor areas and corresponding areas of the brain. The pyramidal tract consists of groups

of crossed nerves located in the white matter of the spinal cord that conduct motor impulses that originate in the opposite area of the brain to the arms and legs. Pyramidal tract nerves regulate both voluntary and reflex muscle movements. In type I, onset is usually before age 25, and affected individuals experience extreme muscle stiffness and rigidity. In type II, onset is typically in the mid-30s, and progressive loss of muscle coordination (ataxia) occurs, resulting in the inability to walk. In type III, the average age of onset is 40 or later, and the main symptoms include weakness and loss of sensation in the legs. While in all types of SCA3 movement and coordination is affected, mental ability is rarely impaired by progression of the disease.

Diagnosis

Diagnosis depends mainly on the clinical history of the family. Because the mutation that causes SCA3 is known, genetic screening to reveal the presence of the increased number of CAG trinucleotide repeats can be useful in cases of persons at risk or when the family history is not known or a person has symptoms that raise suspicion of SCA3. Additionally, imaging studies of the brain using computerized tomography (CT) and magnetic resonance imaging (MRI) may be used to investigate changes in brain physiology and function. Initial diagnosis may be difficult, as people present symptoms easily mistaken for other neurological disorders such as Parkinson and Huntington diseases, or multiple sclerosis.

Treatment and management

Although there is no cure for SCA3, some symptoms can be treated. The medication Levodopa or L-dopa can lessen muscle rigidity and tremors and is often given in conjunction with the drug Carbidopa. However, as the disease progresses and the number of neurons decreases, this treatment becomes less effective. Antispasmodic drugs such as baclofen are also prescribed to reduce spasticity. Dysarthria, or difficulty speaking, and dysphagia, difficulty swallowing, can be treated with proper medication and speech therapy. Physical therapy can help patients with an unsteady gait, but walkers or wheelchairs may be needed as the disease progresses. Other symptoms, such as muscle cramps, urinary disorders, and sleep problems, can also require palliative treatment.

Genetic counseling is recommended for people with a family history of the disease since SCA3 is a dominant inherited disorder.

Prognosis

SCA3 presents a 94.5% penetrance, which means that 94.5% of the people who have the mutation will

QUESTIONS TO ASK YOUR DOCTOR

- My SCA3 has been diagnosed as type II. What does that mean and how does it differ from other types of SCA3?
- Do scientists know the cause of various types of SCA3?
- What treatments are available for my type of SCA3?
- How likely is it that my children will inherit my medical condition?

develop the symptoms during their lives, and less than 5% will remain free of symptoms. Because the intensity and range of symptoms are highly variable among affected individuals, it is difficult to determine the prognosis for a given individual. Because SCA3 can progress slowly, most patients survive until middle age or older.

Spondyloepiphyseal dysplasia

Definition

Spondyloepiphyseal dysplasia is a group of rare hereditary disorders characterized by growth deficiency, spinal malformations, and, in some cases, ocular abnormalities.

Description

Spondyloepiphyseal dysplasia is one of the most common causes of short stature. There are multiple rare and inherited forms of spondyloepiphyseal dysplasia including congenital spondyloepiphyseal dysplasia, X-linked spondyloepiphyseal dysplasia tarda, progressive pseudorheumatoid dysplasia, CHST3-related skeletal dysplasia, pseudoachondroplasia, and hypochondrogenesis. Congenital spondyloepiphyseal dysplasia is primarily characterized by prenatal growth deficiency and spinal malformations. Growth deficiency results in short stature (dwarfism). Abnormalities of the eyes may be present, including nearsightedness (myopia) and retina (the nerve-rich membrane lining the eye) detachment in approximately half of individuals with the disorder. Congenital spondyloepiphyseal dysplasia is inherited as an autosomal dominant genetic trait.

Congenital spondyloepiphyseal dysplasia is also known as SED, congenital type; SED congenita; and SEDC. Spondyloepiphyseal dysplasia tarda primarily affects males. It is characterized by dwarfism and hunched appearance of the spine. The disorder doesn't become evident until five to 10 years of age. Spondyloepiphyseal dysplasia tarda is an X-linked recessive inherited disorder.

Spondyloepiphyseal dysplasia tarda is also known as SEDT; spondyloepiphyseal dysplasia, late; and SED tarda, X-linked.

Other forms of dysplasia are due to mutations in the development, production, and/or proliferation of cartilage, leading to a multitude of abnormalities not just in

the bones and joints but also in the facial features and abdomen due to the wide range of locations and functions of cartilage throughout the body.

Genetic profile

Congenital spondyloepiphyseal dysplasia is thought to probably always result from abnormalities in the *COL2A1* gene, which codes for type II collagen. Collagen is a protein that is a component of bone, cartilage, and connective tissue. A variety of abnormalities (such as deletions and duplications) involving the *COL2A1* gene may lead to the development of the disorder.

It is one of a group of skeletal dysplasias (dwarfing conditions) caused by changes in type II collagen. These include hypochondrogenesis; spondyloepimetaphyseal dysplasia type, Strudwick (SEMD); and Kniest dysplasia. Type 2 collagen is the major collagen of a component of the spine called the nucleus pulposus, of cartilage, and of vitreous (a component of the eye). All of these conditions have common clinical and radiographic findings including spinal changes resulting in dwarfism, myopia, and retinal degeneration.

Congenital spondyloepiphyseal dysplasia is inherited as an autosomal dominant genetic trait. In autosomal dominant inheritance, a single abnormal gene on one of the autosomal chromosomes (one of the first 22 "nonsex" chromosomes) from either parent can cause the disease. One of the parents will have the disease (since it is dominant) and is the carrier. Only one parent needs to be a carrier in order for the child to inherit the disease. A child who has one parent with the disease has a 50% chance of also having the disease.

Autosomal recessive inheritance of congenital spondyloepiphyseal dysplasia has been considered in cases when a child with the disorder is born to parents who are not affected by the disorder. It is considered more likely that in these cases the disorder resulted from germ-line mosaicism in the collagen type II gene of the parent. Germ-line mosaicism occurs when the causal mutation, instead of involving a single germ cell, is carried only by a certain proportion of the germ cells of a given parent. Thus, the parent carries the mutation in his or her germ cells and therefore runs the risk of generating more than one affected child, but does not actually express the disease.

Spondyloepiphyseal dysplasia tarda is caused by mutations in the *TRAPPC2* (also called *SEDL*) gene, which is located on the X chromosome at locus xp22.2-p22.1. This gene provides instructions for producing the protein sedlin, believed to be part of a large molecule called the trafficking protein particle (TRAPP) complex,

known to play a role in the transport of proteins between various cell compartments.

Spondyloepiphyseal dysplasia tarda is inherited as an X-linked disorder. The following concepts are important to understanding the inheritance of an X-linked disorder. All humans have two chromosomes that determine their gender: females have XX, males have XY. X-linked recessive, also called sex-linked, inheritance affects the genes located on the X chromosome. It occurs when an unaffected mother carries a disease-causing gene on at least one of her X chromosomes. Because females have two X chromosomes, they are usually unaffected carriers. The X chromosome that does not have the disease-causing gene compensates for the X chromosome that does. For a woman to show symptoms of the disorder, both X chromosomes would have the disease-causing gene. That is why women are less likely to show such symptoms than males.

If a mother has a female child, the child has a 50% chance of inheriting the disease gene and being a carrier who can pass the disease gene on to her sons. On the other hand, if a mother has a male child, he has a 50% chance of inheriting the disease-causing gene because he has only one X chromosome. If a male inherits an X-linked recessive disorder, he is affected. All of his daughters will be carriers, but none of his sons.

Progressive pseudorheumatoid dysplasia is an autosomal recessive genetic disorder characterized by a mutation in the *WISP3* gene located on the long arm of chromosome 10 that codes for proteins responsible for bone growth and the maintenance of cartilage.

As its name suggests, CHST-related skeletal dysplasia is due to a mutation in the *CHST3* gene. This gene, located on the long arm of chromosome 10, codes for the C6ST-1 enzyme, which is responsible for the development of cartilage. This type of dysplasia is inherited in an autosomal recessive pattern.

Pseudoachondroplasia is an autosomal dominantly inherited dysplasia associated with a mutation of the *COMP* gene, located on the short arm of chromosome 19, which codes for the protein responsible for the normal development of cartilage and the ossification process that cartilage goes through during skeletal immaturity.

Hypochondrogenesis is an autosomal dominantly inherited disorder characterized by a mutation in the *COL2A1* gene located on the long arm of chromosome 12 that is very important in making type 2 collagen. Type 2 collagen is not only important for normal bone growth but also for the cushioning between bones; cartilage of the nose, eyes, and ears; and the cushioning between organs.

Demographics

Spondyloepiphyseal dysplasia is rare, and its incidence is unknown. As of 2015, some 175 cases of congenital spondyloepiphyseal dysplasia had been reported, and roughly 30 individuals with CHST3 type had been reported. Spondyloepiphyseal dysplasia tarda has an incidence estimated at 1 in 150,000 to 200,000 people worldwide, and progressive pseudorheumatoid dysplasia has an incidence of approximately 1 in 1 million in the United Kingdom, with a possible higher incidence in the Middle East. This incidence may be skewed due to the possible misdiagnosis since the signs and symptoms of this dysplasia are very similar to those of juvenile rheumatoid arthritis. The estimated incidence of pseudoachondroplasia is 1 in 30,000. Hypochondrogenesis and another related disorder known as achondrogenesis type 2 have an incidence of 1 in 40,000–60,000 newborns combined.

Congenital spondyloepiphyseal dysplasia affects both males and females. Spondyloepiphyseal dysplasia tarda affects mostly males.

Signs and symptoms

The signs and symptoms of dysplasia generally include abnormal growth and development of bones, joint and cartilage; altered gait; spinal malformations; decreased muscle tone; calcium deposits; clubfeet; flattening of bones; pain in joints; and dislocations. These signs and symptoms range depending on the type of dysplasia inherited. Congenital spondyloepiphyseal dysplasia is characterized by these main features:

- Prenatal growth deficiency occurs prior to birth, and growth deficiencies continue after birth and throughout childhood, resulting in short stature (dwarfism). Adult height ranges from approximately 36–67 in. (91–170 cm).
- Spinal malformations include a disproportionately short neck and trunk and a hip deformity wherein the thigh bone is angled toward the center of the body (coxa vara). Abnormal front-to-back and side-to-side curvature of the spine (kyphoscoliosis) may occur, as may an abnormal inward curvature of the spine (lumbar lordosis). Spinal malformations are partially responsible for short stature.
- Hypotonia (diminished muscle tone), muscle weakness, and/or stiffness is exhibited in most cases.
- Progressive nearsightedness (myopia) and/or retinal detachment may develop. Retinal detachment, which can result in blindness, occurs in approximately 50% of cases.
- An abnormally flat face, underdevelopment of the cheekbone (malar hypoplasia), and/or cleft palate may

present in some individuals with congenital spondyloepiphyseal dysplasia.

- Additional associated abnormalities may include underdevelopment of the abdominal muscles; a rounded, bulging chest (barrel chest) with a prominent sternum (pectus carinatum); diminished joint movements in the lower extremities; the heel of the foot may be turned inward toward the body while the rest of the foot is bent downward and inward (clubfoot); and, rarely, hearing impairment due to abnormalities of the inner ear.

The hypotonia, muscle weakness, and spinal malformations may result in a delay in affected children learning to walk. In some cases, affected children may exhibit an unusual “waddling” gait.

Symptoms of spondyloepiphyseal dysplasia tarda are not usually apparent until five to 10 years of age. At that point, a number of symptoms begin to appear:

- abnormal growth causes mild dwarfism
- spinal growth appears to stop and the trunk is short
- the shoulder may assume a hunched appearance
- the neck appears to become shorter
- the chest broadens (barrel chest)
- additional associated abnormalities may include unusual facial features such as a flat appearance to the face; progressive degenerative arthritis may affect hips and other joints of the body

Spine and hip changes become evident between 10 and 14 years of age. In adolescence, various skeletal abnormalities may cause pain in the back, hips, shoulders, knees, and ankles; a large chest cage; and relatively normal limb length. In adulthood, height usually ranges from 52 to 62 inches; hands, head, and feet appear to be of normal size.

Progressive pseudorheumatoid dysplasia is a progressive form of dysplasia, meaning the symptoms worsen over time and is characterized by the degradation of bone over time. This type of dysplasia usually presents itself clinically between the ages of three and eight with pain in joints and altered gait, which may develop into other spinal abnormalities including but not limited to platyspondyly, increased curvatures of the spine, short stature, and abnormal calcium deposits within or around joints.

CHST3-related skeletal dysplasia is another form of progressive bone and joint dysplasia, characterized by dwarfism and joint dislocations present at birth with or without cardiac complications and abnormalities.

Pseudoachondroplasia is a congenital dysplasia similar to achondroplasia without characteristic facial features. Typical bone abnormalities associated with this

KEY TERMS

Cleft palate—A congenital malformation in which there is an abnormal opening in the roof of the mouth that allows the nasal passages and the mouth to be improperly connected.

Coxa vara—A deformed hip joint in which the neck of the femur is bent downward.

Dysplasia—The abnormal growth or development of a tissue or organ.

Epiphyseal—The region of the bone responsible for growth of the bone.

Hypotonia—Reduced or diminished muscle tone.

Kyphoscoliosis—Abnormal front-to-back and side-to-side curvature of the spine.

Lumbar lordosis—Abnormal inward curvature of the spine.

Malar hypoplasia—Small or underdeveloped cheekbones.

Myopia—Nearsightedness. Difficulty seeing objects that are far away.

Ochronosis—A condition marked by pigment deposits in cartilage, ligaments, and tendons.

Ossification—The process of the formation of bone from its precursor, a cartilage matrix.

Retina—The light-sensitive layer of tissue in the back of the eye that receives and transmits visual signals to the brain through the optic nerve.

type of dysplasia include but are not limited to short stature shown by the age of two, joint pain, hypermobility, varus/valgus deformity of the arms and/or legs, and an alteration in the spinal curvatures.

Hypochondrogenesis is a severe form of dysplasia characterized by short stature, short extremities, and ossification of the joints of the spine and pelvis. This form of dysplasia also affects the development of other cartilage related tissues such as in the facial and abdominal structures. Due to widespread malformation, the prognosis of hypochondrogenesis is very poor, with infants dying soon after birth from respiratory complications.

Diagnosis

X-rays may be used to diagnose spondyloepiphyseal dysplasia when it is suspected, utilizing the cardinal signs of each type of dysplasia. Genetic sequencing may also be utilized to distinguish between the different types of

dysplasias as well as from other bone and joint disorders with similar clinical presentations.

Individuals with congenital spondyloepiphyseal dysplasia have characteristic x-rays that show delayed ossification of the axial skeleton with ovoid vertebral bodies. With time, the vertebral bodies appear flattened. There is delayed ossification of the femoral heads, pubic bones, and heel. The coxa vara deformity of the hip joint is common.

It should be noted that x-rays of individuals with spondyloepimetaphyseal dysplasia type Strudwick are virtually identical to congenital spondyloepiphyseal dysplasia. In early childhood, irregularity in the region beneath the ends of bones (metaphyseal) and thickening of the bones (sclerosis) are noted in spondyloepimetaphyseal dysplasia type Strudwick. Also, there is platyspondyly (flattened vertebral bodies) and odontoid hypoplasia.

Radiologic diagnosis of spondyloepiphyseal tarda cannot be established before four to six years of age. Symptoms usually begin to present between five and ten years of age. Symptomatic changes in the spine and hips usually present between 10 and 14 years of age.

In adults, vertebral changes, especially in the lumbar region, may be diagnostic. Ochronosis (pigment deposits in cartilage, ligaments, and tendons) is suggested by apparent intervertebral disc calcification, and the vertebral bodies are malformed and flattened with most of the dense area part of the vertebral plate.

Treatment and management

Individuals with spondyloepiphyseal dysplasia should be under routine health supervision by a physician who is familiar with the disorder, its complications, and its treatment as related to the specific form of dysplasia present.

Congenital spondyloepiphyseal dysplasia

Treatment is mostly symptomatic, and may include the following:

- Orthopedic care throughout life. Early surgical interventions may be needed to correct clubfoot and/or cleft palate. Hip, spinal, and knee complications may occur, and hip replacement is sometimes warranted in adults. Additionally, arthritis may develop due to poorly developed type II collagen. Spinal fusion may be indicated if evaluation of the cervical vertebrae C1 and C2 detects odontoid hypoplasia. (If the odontoid is hypoplastic or small, it may predispose to instability and spinal cord compression in congenital spondyloepiphyseal dysplasia).

QUESTIONS TO ASK YOUR DOCTOR

- What type of dysplasia does my child have and what is the prognosis?
- Other than reduced growth, what physical or mental abnormalities are associated with spondyloepiphyseal dysplasia?
- How does this condition affect a person's lifespan and activities of daily living?
- What type of medical surveillance is needed for a person with spondyloepiphyseal dysplasia during his or her lifetime?
- What are the risks and benefits of having surgery for lengthening arm and leg bones?
- What other treatment and management options are available for my child?

- Ophthalmologic examinations are important for the prevention of retinal detachment and treatment of myopia and early retinal tears if they occur.
- Hearing should be checked and ear infections should be closely monitored. Tubes may need to be placed in the ear.
- Due to neck instability, persons with SEDC should exercise caution to avoid activities/sports that could result in trauma to the neck or head.

Individuals with congenital spondyloepiphyseal dysplasia should be closely monitored during anesthesia and for complications during a respiratory infection. In particular, during anesthesia, special attention is required to avoid spinal injury resulting from lax ligaments causing instability in the neck. This condition may also result in spinal injury in contact sports and car accidents. Chest constriction may also cause decreased lung capacity.

Spondyloepiphyseal dysplasia tarda

Treatment is mostly symptomatic, and may include the following:

- Physical therapy to relieve joint stiffness and pain.
- Orthopedic care may be needed at different times throughout life. Bone changes of the femoral head often lead to secondary osteoarthritis during adulthood and some patients require total replacement of the hip before the age of 40 years.

Some individuals with short stature resulting from spondyloepiphyseal dysplasia may consider limb-lengthening surgery. This is a controversial surgery that

lengthens leg and arm bones by cutting the bones, constructing metal frames around them, and inserting pins into them to move the cut ends apart. New bone tissue fills in the gap. While the surgery can be effective in lengthening limbs, various complications may occur.

Genetic counseling

Genetic counseling may be of benefit for patients and their families.

In congenital spondyloepiphyseal dysplasia, only one parent needs to be a carrier in order for the child to inherit the disorder. A child has a 50% chance of having the disorder if one parent has the disorder and a 75% chance of having the disease if both parents have congenital spondyloepiphyseal dysplasia.

In spondyloepiphyseal dysplasia tarda, if a mother has a male child, he has a 50% chance of inheriting the disease-causing gene. A male who inherits an X-linked recessive disorder is affected, and all of his daughters will be carriers, but none of his sons.

Prenatal testing

Prenatal testing may be available to couples at risk for bearing a child with spondyloepiphyseal dysplasia. Testing for the genes responsible for congenital spondyloepiphyseal dysplasia and spondyloepiphyseal dysplasia tarda is possible. Congenital spondyloepiphyseal dysplasia testing may be difficult, however, since although the gene has been located, there is variability in the mutations in the gene among persons with the disorder.

Either chorionic villus sampling (CVS) or amniocentesis may be performed for prenatal testing. CVS is a procedure to obtain chorionic villi tissue for testing. Examination of fetal tissue can reveal information about the defects that lead to spondyloepiphyseal dysplasia. CVS can be performed at 10–12 weeks gestation.

Amniocentesis is a procedure that involves inserting a thin needle into the uterus, into the amniotic sac, and withdrawing a small amount of amniotic fluid. DNA can be extracted from the fetal cells contained in the amniotic fluid and tested. Amniocentesis is performed at 16–18 weeks gestation.

Prognosis

Prognosis is variable dependent upon severity of the disorder. Generally, congenital spondyloepiphyseal dysplasia is more symptomatic than spondyloepiphyseal dysplasia tarda. Neither form of the disorder generally leads to shortened lifespan. Cognitive function is generally normal. The prognosis of hypochondrogenesis is very poor, with infants dying soon after birth from respiratory

complications. Those patients who do live with this type of hypochondrogenesis are then reclassified as having congenital spondyloepiphyseal dysplasia.

Spondyloepiphyseal dysplasia congenita

Definition

Spondyloepiphyseal dysplasia congenita (SEDC) is a form of dwarfism (achondroplasia) that is caused by a gene mutation interfering with prenatal bone development. People with SEDC have a short physique, misshaped bones, and a flattened face. The name for this

condition was derived from the Greek words “spondylos” (referring to the spine) and “epiphyseal” (referring to the formative areas of the bones). The Greek word “dysplasia” refers to abnormal tissue formation.

Description

This disorder is caused by a mutation on the gene responsible for producing collagen II. Collagen II is an organic gel that influences the transformation of cartilage into bone. It is also essential in developing the lubricants of the joints and the eyes. People with SEDC are affected mostly in the development and structure of their bones. Almost half suffer from myopia, or nearsightedness. There is no effect on intellectual function.

SEDC is distinguished from other forms of achondroplasia by its onset at birth and by the mutation causing it. Spondyloepiphyseal dysplasia tarda is not observable until later in life. The most notable feature of SEDC is the short stature of those affected. Other observable features are a skeletal framework that is not properly aligned and that has an abnormal shape, the chest is barrel shaped, and the trunk and the neck are unusually short.

Genetic profile

The skeletal disorder SEDC is caused by a mutation in the *COL2A1* gene on chromosome 12. This gene is responsible for producing collagen II, which is essential in the development of the lubricants for the bones and eyes. It is also involved in the prenatal development of bone from cartilage. Any mutation in the *COL2A1* gene interferes with proper development of bones and, more generally, the skeletal system. Because the mutation produces an autosomal dominant trait, only one gene with the mutation is necessary for the condition to occur. Most observed cases are from sporadic mutations, which means that the parents had normal genes that for some reason mutated. However, a person with the mutation could pass it on to offspring who would then have a 50% chance of developing the condition, given that both parents do not have the disorder.

The siblings of affected individuals have no chance of passing the trait on to their children. If both parents have the mutated genes, there is a 50% chance that either one will pass on the gene to the child who will then develop SEDC. There is a 25% chance that neither parent will pass on the gene; the child will grow normally. However, there is a 25% chance that both will pass on the gene; in this case, the child is not likely to survive the first few years of life.

Demographics

This condition is most often caused by a sporadic mutation; therefore, it is very rare. It is estimated that it is observed in only 1 out of 100,000 births. Although the exact number is not known, scientific literature has reports of more than 175 cases. The gene responsible for this disorder has been determined to be autosomal dominant. This means that it is not sex related; men and women are equally affected. Because most cases are due to a sporadic mutation, there are no racial trends in its occurrence, as is true for most cases of achondroplasia.

Signs and symptoms

Some of the expected characteristics of people with SEDC include the following:

- shortened limbs
- average-sized hands and feet
- abnormal spine curvature
- vertebral instability in the neck
- flattened vertebrae
- bow legs
- early onset of arthritis
- flattened face

Other characteristics may include the following:

- clubfoot in one or both feet
- moderate hearing loss
- lack of muscle tone
- cleft palate

Some of the common deformities that continue to cause problems throughout a person's life include hip and knee irregularities that may cause pain in the joints and contribute to abnormal walking patterns. Many people with SEDC suffer from spinal deformities that contribute to breathing and standing problems. Most have a curvature of the spine to some degree. Spinal deformities contribute to a rigid posture and uncontrollable spasms throughout the skeletal system. Spinal cord compression can result from these deformities, creating even more complications.

Diagnosis

There are signs of this form of achondroplasia that are observable from birth. However, ascertaining that this condition is actually SEDC with its accompanying complications is only possible through a blood test. Unlike other congenital forms of achondroplasia, babies with SEDC show signs of the disorder; they tend to have a flattened spine and a flattened face because of poorly developed facial muscle. The short stature, along with the

disproportionate ratio of head to body and trunk to body, indicates that the baby has some form of achondroplasia; the face and spine indicate that it is very likely SEDC.

Because these characteristics are observed at birth, the question arises, “Why are they not observable through the prenatal ultrasound?” Most ultrasound images of the developing fetus are not powerful enough to detect the subtle features that would suggest achondroplasia, or more specifically SEDC.

As the child with SEDC grows, development must be constantly assessed. Normal scale of development, particularly motor development, may indicate delays. However, there should be normal development expected for cognitive and language development. All areas of motor and skeletal development should be constantly assessed, including signs for spinal cord compression, motor weakness, problems with walking, and a lack of physical endurance. The prevalent curvature of the spine is expected to increase with age and should be continuously assessed as it tends to lead to problems with flexibility in the hips. Any deformation observed at birth or with later development has a strong likelihood of contributing to later deterioration of any part of the skeletal system. Particular attention should be given to problems of the hips.

Treatment and management

Because most cases are unpredictable due to a spontaneous mutation, it is not easy to detect SEDC before birth. The differences suggesting SEDC are too subtle in the developing fetus to detect in the womb by ultrasound. However, recent research conducted at the Clinical School of Medical College, Nanjing University in China has demonstrated that detection through analysis of amniotic fluid is possible. Detecting the mutation for SEDC is not usually a goal of typical amniocentesis because the condition is so rare. Prenatal counseling is recommended for a couple when one or both are carriers of the mutated gene. It is also recommended when the father is over 56 years of age, because more mutations take place in the sperm of older men.

Although there are some forms of achondroplasia that respond well to growth therapies, the treatment for SEDC and most forms of achondroplasia is not focused on increasing physical stature. Because SEDC is not a result of growth hormone deficiency, growth therapies would not be appropriate. The various treatments for SEDC are concerned with easing associated disabilities and delaying any perceived deterioration.

Traditional treatment

The usual treatment for children with any form of achondroplasia is continuous evaluations by a team of specialists. This is especially true for the child with SEDC

QUESTIONS TO ASK YOUR DOCTOR

- What corrective surgery should I expect?
- How do other people with SEDC cope with daily living skills?
- Is genetic counseling important for my situation?
- What are the chances that a child of mine will be born with SEDC?
- How often should I be physically evaluated per year?
- What do I do when conditions get worse?

who has to face the strong possibility of deterioration in sight, hearing, breathing, and motor function. Orthopedic surgery is a certainty; however, physical therapy and adaptive devices may reduce the number of operations necessary. Some of the more common adaptive devices include leg braces, forearm crutches, and orthopedic footwear.

Some of the purposes of orthopedic surgery include procedures to help steer growing bones into the appropriate direction. Another procedure designed for straightening out a crooked bone involves breaking the bone and then resetting it as straight. Metal plates are inserted to hold it in the corrected position. Surgery to correct the curved spine is common, as well as surgery to offset spinal compression.

In recent years there have been experiments to lengthen the limbs of people with achondroplasia. This procedure is controversial because it means having the child undergo surgery and does not resolve the underlying problems of SEDC and undergoing the procedure implies that there is something wrong with short height. In this surgical procedure, a bone is broken and the two parts of the bone are attached to a metal rod. The bone is expected to grow around the rod and the limb is expected to stretch to accommodate the new length. However, the deficiency of collagen II still exists for the person undergoing this surgery. The bone cannot grow at a normal or predictable rate. The deterioration and lack of lubrication in the joints will still continue.

Prognosis

The first point in considering the prognosis for a person born with SEDC is that there is no cure. A baby born with SEDC will still have the condition into adulthood. For the most part, life expectancy is no different for someone born with SEDC than for the general population. There are two exceptions. The first exception is that

the child who inherits the mutated gene from both parents is not likely to live past the third birthday. However, since most cases are due to sporadic mutations, this situation is very rare. The other exception is that neck injuries pose a greater threat for the person with SEDC. Thus, children with the disorder must be extremely careful in situations that could cause neck injuries.

Ray F. Brogan, PhD

SRY (sex-determining region Y)

Definition

The sex-determining region Y (*SRY*) gene is located on the Y chromosome. *SRY* is the main genetic switch

Flow chart of male and female sex differentiation from conception through development. (Gale)

for the sexual development of the human male. If the *SRY* gene is present in a developing embryo, typically it will become male.

Description

The development of sex in a human depends on the presence or absence of a Y chromosome. Chromosomes are the structures in our cells that contain genes. Genes instruct the body on how to grow and develop by making proteins. For example, genes (and the proteins they make) are responsible for what color hair or eyes people may have, how tall they will be, and what color skin they will have. Genes also direct the development of organs, such as the heart and brain. Genes are constructed out of DNA, deoxyribonucleic acid. DNA is found in the shape of a double helix, like a twisted ladder. The DNA contains the "letters" of the genetic code that make up the "words" or genes that govern the development of the body. The genes are found in the "books" or chromosomes in the cells.

Normally, there are 46 chromosomes, or 23 pairs, in each cell. The first 22 pairs are the same in men and women and are called the autosomes. The last pair, the sex chromosomes, consists of two X chromosomes in females (XX) and an X and a Y chromosome in males (XY). These 23 pairs of chromosomes contain approximately 35,000 genes.

Human males differ from human females in the fact that they have a Y chromosome, and females do not. Scientists thought there must be a gene on the Y chromosome that is responsible for determining maleness. The gene for determining maleness was called *TDF* for testis-determining factor. In 1990, the *SRY* gene was found and scientists believed it was the *TDF* gene they had been looking for. The evidence scientists had to show *SRY* was indeed *TDF* included the fact that it was

KEY TERMS

Cartilage—Supportive connective tissue that cushions bone at the joints or that connects muscle to bone.

Embryo—The earliest stage of development of a human infant, usually used to refer to the first eight weeks of pregnancy. The term “fetus” is used from roughly the third month of pregnancy until delivery.

Epididymis—Coiled tubules that are the site of sperm storage and maturation for motility and fertility. The epididymis connects the testis to the vas deferens.

Gonad—The sex gland in males (testes) and females (ovaries).

Hormone—A chemical messenger produced by the body that is involved in regulating specific bodily functions such as growth, development, and reproduction.

Nucleus—The central part of a cell that contains most of its genetic material, including chromosomes and DNA.

Ovary—The female reproductive organ that produces the reproductive cell (ovum) and female hormones.

Seminal vesicles—The pouches above the prostate that store semen.

Testes—The male reproductive organs that produce male reproductive cells (sperm) and male hormones.

Vas deferens—The long, muscular tube that connects the epididymis to the urethra through which sperm are transported during ejaculation.

located on the Y chromosome. When *SRY* was found in individuals with two X chromosomes (normally females), these individuals had male physical features. Furthermore, some individuals with XY sex chromosomes that had female physical features had mutations or alterations in their *SRY* gene. Finally, experiments were done on mice that showed a male mouse would develop when *SRY* was put into a chromosomally female embryo. This evidence proved that *SRY* is the *TDF* gene that triggers the pathway of a developing embryo to become male. While the *SRY* gene triggers the pathway to the development of a male, it is not the only gene responsible for sexual development. Most likely, the *SRY* gene serves to regulate the activity of other genes in this pathway.

Genetic profile

Men and women both have 23 pairs of chromosomes—22 pairs of autosomes and one pair of sex chromosomes (either XX in females or XY in males). The *SRY* gene is located on the Y chromosome. When a man and a woman have a child, it is the man’s chromosomes that determine if the baby will be male or female. This is because the baby inherits one of its sex chromosomes from the mother and one from the father. The mother has only X chromosomes to pass on, while the father can pass on either his X chromosome or his Y chromosome. If he passes on his X chromosome, the baby will be female. If he passes on his Y chromosome (with the *SRY* gene) the baby will be male. Statistically, each pregnancy has a 50% chance of being female and a 50% chance of being male. The Y chromosome is the smallest human chromosome and the SRY region contains a very small number of genes.

Signs and symptoms

Individuals with point mutations or deletions of the *SRY* gene have a condition known as gonadal dysgenesis, XY female type, also called Swyer syndrome. At birth, the individuals with the XY female type of gonadal dysgenesis appear to be normal females (with female inner and outer genitalia); however, they do not develop secondary sexual characteristics at puberty, do not menstruate, and have “streak” (undeveloped) gonads. They have normal stature and an increased incidence of certain neoplasms (gonadoblastoma and germinoma).

Normal development

In normal human sexual development, there are two stages called determination and differentiation. Determination occurs at conception when a sperm from a man fertilizes an egg from a woman. If the sperm has a Y chromosome, the conception will eventually become male. If no Y chromosome is present, the conception will become female.

Though the determination of sex occurs at conception, the differentiation of the developing gonads (future ovaries in the female and testes in the males) does not occur until about seven weeks. Until that time, the gonads look the same in both sexes and are called undifferentiated or indifferent. At this point in development, the embryo has two sets of ducts: the Mullerian ducts that form the fallopian tubes, uterus and upper vagina in females and the Wolffian ducts that form the epididymis, vas deferens, and seminal vesicles in males.

In embryos with *SRY* present, the undifferentiated gonads will develop into the male testes. The testes produce two hormones that cause the differentiation into

maleness. Mullerian inhibiting substance (MIS), also called anti-Mullerian hormone (AMH), causes the Mullerian ducts to regress and the Wolffian ducts to develop into the internal male structures. Testosterone also helps with the development of the Wolffian ducts and causes the external genitals to become male.

When *SRY* is not present, the pathway of sexual development is shifted into female development. The undifferentiated gonads become ovaries. The Mullerian ducts develop into the internal female structures and the Wolffian ducts regress. The external genitals do not masculinize and become female.

SRY and male development

How the *SRY* gene causes an undifferentiated gonad to become a testis and eventually determine the maleness of a developing embryo is not completely understood. What scientists believe happens is that *SRY* is responsible for “triggering” a pathway of other genes that cause the gonad to continue to develop into a testis. The SRY protein is known to go into the nucleus of a cell and physically bend the DNA. This bending of DNA may allow other genes to be turned on that are needed in this pathway. For example, anti-Mullerian hormone is thought to be indirectly turned on by *SRY*.

It is also thought that a threshold exists that must be met at a very specific time for *SRY* to trigger this pathway. This means that enough SRY protein must be made early in development (before seven weeks) to turn an undifferentiated gonad into a testis. If enough SRY is not present or if it is present too late in development, the gonad will shift into the female pathway.

Other genes in sex development

Several other genes have been found that are involved in the development of human sex, including the gene *SOX9*. Mutations or alterations in this gene can cause a condition called camptomelic dysplasia. People with camptomelic dysplasia have bone and cartilage changes. *SOX9* alterations also cause male to female sex reversal in most affected individuals (male chromosomes and female features). It is not known how *SRY*, *SOX9*, and other genes in the sexual developmental pathway interact to turn an undifferentiated gonad into a testis or an ovary.

Stargardt disease

Definition

Stargardt disease (STGD) is an inherited vision disorder with macular degeneration that typically affects younger people.

Description

STGD is the most common form of inherited macular degeneration (or dystrophy), a disorder of the retina, that affects younger people. The condition is also known as Stargardt macular dystrophy, juvenile macular degeneration, macular dystrophy with flecks, and fundus flavimaculatus.

Common symptoms of STGD include progressive loss of central vision, problems identifying and differentiating colors, and difficulty seeing fine details clearly.

A retinal photograph showing Stargardt disease. (Kokell/BSIP SA/Alamy)

Genetic profile

There are different types of STGD. The most common form is Type 1, which is associated with autosomal recessive inheritance. In this type, there may be no family history of the condition, and it usually affects only one generation. A couple has a 25% chance of having another affected son or daughter once a child is diagnosed with STGD Type 1. This type of STGD is associated with mutations in the *ABCA4* (or *ABCR*) gene, which is located on chromosome 1. This gene is involved in moving vitamin A compounds naturally to and from cells in the retina; these cells are often impaired in STGD.

Other rarer forms of macular dystrophy with symptoms nearly identical to STGD have been called Stargardt-like macular dystrophy Types 2, 3, and 4. These are associated with autosomal dominant inheritance. In these types, a family history of the condition is quite common and STGD may be present in several generations of a family tree. A parent with these macular dystrophies has a 50% chance of having an affected son or daughter. Some of these individuals have been found to have mutations in the *ELOVL4* gene on chromosome 6.

Demographics

STGD is found worldwide, affecting males and females equally. The incidence for Type 1 is estimated to be between 1 in 1,600 and 1 in 15,000 individuals. In all, it accounts for 7% of all retinal dystrophies.

STGD Type 1 is usually diagnosed in individuals under the age of 20 when decreased central vision is the first problem noticed. In contrast, Stargardt-like macular dystrophies and age-related macular degeneration typically first show up in adulthood.

Signs and symptoms

Each person with STGD experiences symptoms differently. STGD affects the macula, a specialized portion of the retina that is highly responsible for the ability to see straight in front, notice colors, and see fine details. The macula is normally full of photoreceptors called cone cells. Cone cells help process the light rays that naturally hit the retina. In STGD, these cone cells slowly begin to die and lose function. In addition, the macula's appearance may begin showing abnormal yellow-white flecks that are shaped irregularly in people who have STGD.

Problems with central vision may be an early sign of STGD. The progression of this varies from person to person, and is impossible to predict. In addition, one's ability to see clearly (visual acuity) becomes progressively worse over time. This can progress from near-normal visual acuity to legal blindness. By the age of 50 years,

KEY TERMS

Dystrophy—Progressive abnormal changes in a tissue or organ.

Fluorescein angiography—Procedure to look at the blood vessel system of the eye. Fluorescein, a dye, is injected and photographs are taken as the dye passes through the eye's blood vessels.

Fundus—The interior back wall of the eyeball.

Macular degeneration—Progressive condition that affects the macula, a small portion of the retina at the back of the eye.

Mutation—Small change in the sequence of a gene.

Photoreceptor—Cells at the back of the eye that process the light that hits them; examples are cone and rod cells.

Retina—Structure at the back of the eye with multiple layers, containing different types of cells.

about half of people with STGD have visual acuity equal to or worse than that of legal blindness. Unfortunately, the reduced visual acuity in STGD cannot usually be corrected with prescription eyeglasses or contact lenses.

In later stages of STGD, color vision can be impacted. People may have trouble identifying colors or distinguishing them from one another. Rarely, people may experience difficulty with brightly lit conditions, blind spots in their vision, and problems with adjusting to dark environments.

Diagnosis

A diagnosis is most commonly made based on a person's symptoms. However, genetic testing is available to those suspected to have the condition. A few laboratories offer molecular testing of the *ABCA4* and *ELOVL4* genes on a clinical basis. Still others offer testing of these genes as part of a research study.

A young person who complains of problems with central vision or has poor visual acuity that cannot be corrected should be tested for STGD. A combination of various visual investigations can help rule out other diagnoses and identify visual problems that are consistent with STGD.

A detailed eye examination with an ophthalmologist can help determine one's visual acuity and general eye health. The physician may want to track the visual acuity over time to determine whether it can be corrected with prescription eyeglasses or contact lenses. The

ophthalmologist may also order visual tests to get more information about a diagnosis.

Testing of the visual fields can determine how much is being seen from left to right, and up and down. The full field of vision is studied to identify any blind spots or clarify whether the central vision is affected.

Fluorescein angiography (FA) can be helpful to determine whether blood flow is normal throughout the back of the eye. These detailed photographs of the eye's blood vessels can help identify any circulatory problems at the back of the eye, as well as changes in the retina's structure.

Fundus photographs can be taken to document changes in the eye structure, shape, and color. In STGD, this can sometimes show the yellowish-white flecks on the retina, which may actually fade with time. Sometimes there are other color changes in the retina of people with STGD as well.

An electroretinogram (ERG) tests how well the photoreceptors in the retina are functioning. Specifically for STGD, this test is very good at identifying how well the cone cells are working. It can also show how a person with STGD progressively loses working cone cells.

An electro-oculogram is similar to an ERG in that it studies retinal function and health. However, it is also meant to study the natural connection that exists between the eye and brain. This pathway must function normally in order for people to recognize an image that their eye sees. For STGD, this type of test can further document the cone cell abnormalities or loss.

STGD should not be confused with age-related macular degeneration (AMD), a relatively common condition in individuals often past the age of 50 years. Though the symptoms may be very similar, AMD has not been found to be associated with mutations in the *ABCA4* or *ELOVL4* genes.

Treatment and management

There is no cure for STGD, or known way to stop the disease progression altogether. However, some things can help maintain good retinal function and health.

It is felt that a diet rich in leafy green vegetables and fish may be good for the retina. In addition, certain fish contain omega-3 fatty acids, such as docosahexaenoic acid (DHA), that is naturally found in the retina in very high concentrations. Eating a diet of fish like salmon, tuna, mackerel, or whitefish twice a week should naturally provide good DHA levels. Otherwise, good fish oil capsules containing DHA and other omega fatty acids can be obtained with a prescription or purchased at specialty health stores.

Multivitamins containing vitamins A, E, and C may be useful. These have antioxidant properties, which may be protective for the eyes. However, large doses of certain vitamins may be toxic, and affected individuals should speak to their doctors before taking supplements.

Protecting the eyes from harmful ultraviolet rays is essential to cone cell health. People with STGD should wear good sunglasses outdoors and especially when over water or near snow on a bright, sunny day.

Smoking has been associated with deteriorating retinal health. Even quitting smoking late in life can make a positive impact on eye health.

Low vision aids can be helpful for those in school or at work. Binocular lens and magnifying screens, large-print reading materials, closed-circuit television, and other tools can be helpful and are often available from organizations supporting those with vision loss.

Living with a chronic vision problem makes a significant impact on a person's life and family. It is often helpful for families to have a social worker connect them to helpful resources. Others may find genetic counseling, psychotherapy, or meeting other individuals with STGD through support groups helpful.

Prognosis

Life expectancy is normal in STGD. A person's vision loss is progressive, but the rate of this is unpredictable. Research and future treatments continue to offer hope for those with this type of macular dystrophy.

Stem cells

Definition

Stem cells are cells from the adult or embryo that can develop into many different types of cells and have the ability to replicate themselves.

Description

Types of stem cells

Stem cells can be found in every organ and tissue of the body. They have the ability to develop into many different cell types. There are four types of stem cells:

1. Embryonic stem cells. Embryonic stem cells are pluripotent, which means that they can make copies of themselves indefinitely and can develop into any type of cell in the body. In humans, they first develop into neuroectoderm and mesendoderm precursor cells. Neuroectoderms develop into nerve cells. Mesendoderms develop into all the other cells of the body that makeup organs, muscles, blood and bone. Embryonic cells for research, come from three-to-five-day-old embryos donated from in vitro fertilization procedures (IVF).
2. Perinatal stem cells. Stem cells have been found in the amniotic fluid that surrounds the baby and in umbilical cord blood. These stem cells are pluripotent cells and act like embryonic stem cells.
3. Adult stem cells. A few of these stem cells are found in most tissues. They have a more limited ability to develop into other types of cells.

4. Induced pluripotent adult stem cells. These are adult stem cells whose genes have been changed so that they act like embryonic stem cells. They can make copies of themselves and can develop into most types of cell in the body. Induced pluripotent adult stem cells have limitations. Scientists have not yet been able to develop an adult pluripotent stem cell that can develop into any type of cell.

Stem cell uses

The first stem cells, discovered in 1981, were embryonic stem cells from mice. In 1998 scientists were first able to isolate and grow human embryonic stem cells in the lab. In 2006 researchers first created induced pluripotent adult stem cells. Ever since the discovery of stem cells, researchers have been investigating ways to use stem cells to cure disease, create new organs, and repair damaged tissue.

Stem cell treatments for cancer

Stem cells from the blood are already being used to help replace blood cells damaged by cancer and cancer treatments. Blood stem cells develop into different cells as they mature. They develop into platelets that help your blood clot, red blood cells which deliver oxygen to your body and white blood cells that fight off illness.

Stem cells and mature blood cells can be damaged by cancer and cancer treatment. The stem cells can be replaced with stem cells from healthy donors (allogeneic) or from a person's own stem cells (autologous).

During an allogenic transplant the patient first gets matched to a donor who has a similar genetic makeup. This can help prevent rejection of the donated cells. Alternatively, stem cells from donated umbilical cord blood can be used. The allogenic transplant is done after the patient has treatment like radiation or chemotherapy

A color-enhanced scanning electron microscope image of a stem cell and its processes. (MedicalRF/Science Source)

that destroys the patient's own stem cells. The donor stem cells will be transplanted to the patient's blood stream through an IV. The donor stem cells will then develop into mature and healthy blood cells.

During an autologous transplant, healthy stem cells will be taken from the patient's bone marrow or blood and then frozen. Once the patient's cancer treatment is completed, their stem cells will be returned to the blood stream. The stem cells will eventually develop back into mature blood cells.

Research on how diseases occur

Scientists watch how stem cells mature into different cells of the body and organs and tissues. This allows them to gain a better understanding of how diseases develop and research what causes genetic defects in cells. It can also allow them to discover why certain cells become cancerous.

Regenerative medicine

Regenerative medicine involves methods to repair or replace damaged cells tissues or organs. A lot of research in the field of regenerative medicine involves the use of stem cells. Most researchers believe that stem cells will one day routinely be grown in the lab, manipulated to develop into a specific cell like heart muscle or nerve cells, and then transplanted into diseased or damaged tissue. Stem cells may also one day be used to create organs, which would reduce our reliance on often expensive and difficult-to-obtain donor organs.

Scientists have already demonstrated that they can manipulate stem cells from the blood to grow into cells that can be injected into the heart and repair damage from heart attacks. The use of stem cells to repair damaged tissue would be particularly helpful for tissue like nerve cells or cartilage in the nose, ears, and joints since it does not regenerate on its own.

Gene therapies

Gene therapy involves treating a disease by adding, removing, or changing the genetic material in the cells of a patient. It is often used to treat genetic disease by correcting an abnormal gene that is not functioning properly. Somatic gene therapy involves adding, removing, or changing the genetic material in tissue or cells. This results in the production of a naturally occurring protein that is lacking or not functioning correctly in an individual patient.

Gene therapy can be done using mature cells or stem cells. The advantage of using stem cells is that they can self renew, last longer outside of the body, and differentiate into different cell types.

KEY TERMS

Cell—Building block that provides structure to the body and performs all the functions of the body. Cells contain genetic information and can copy themselves. The four main types of cells are: skin, nerve, muscle and connective tissue.

Gene—A gene is the unit of information on DNA that contains the instructions for making a protein.

Genome—The complete set of genetic instructions of an organism.

Induced pluripotent stem cells—Adult stem cells whose genes have been changed so that they act like embryonic stem cells. They can make copies of themselves indefinitely and can develop into many types of cell.

Pathogenic variant—Any change in the sequence of a genome that causes disease.

Pluripotent stem cells—Can develop into any type of cell in the body and have the ability to replicate themselves.

Protein—Proteins are the building blocks for life. They guide the development and functioning of the body.

Stem cells—Cells that can transform into any different type of cell and can make copies of themselves indefinitely.

Tissue—Made up of cells that have a common function. The four types of tissue are: connective, epithelial (skin), muscle and nervous tissue.

Variant—Change in the sequence of a genome.

Although gene therapy can be done directly in the body (in vivo), gene therapy using stem cells is typically done outside of the body (ex vivo). In ex vivo gene therapy, cells are genetically modified in the lab and then transplanted back into the body.

Gene therapies using stem cells can be done using donor stem cells or stem cells from the patient. Using stem cells from the patient is advantageous since it can be hard to find donors that are a close genetic match. Also, using ones own cells reduces the risk that the body will reject the stem cells as foreign. Because of these challenges, researchers often prefer using gene therapy on stem cells derived from the patient.

Gene therapy using stem cells can be used to treat many genetic conditions. It is particularly useful for conditions where the body is not producing enough of a

certain type of protein. For example, successful clinical trials have been done on Fabry disease. Fabry disease is caused by a genetic defect that reduces the amount of functioning GLA protein. This protein normally breaks down certain types of fats. When GLA is not functioning correctly, then these fats can accumulate in the organs causing problems in the kidneys, heart and brain.

In one gene therapy trial, blood stem cells were removed from patients with Fabry disease. A functioning gene was inserted into the stem cells that allowed them to create normal GLA. The newly modified stem cells were then transplanted back into each patient. All participants in the trial began producing near normal amounts of fully functioning GLA within one week and were able to stop their other treatments.

Another trial involved nine patients with leukodystrophy, a severe degenerative disease that affects the nerve cells and typically causes death in childhood. Participants in this trial all had a form of leukodystrophy that results from pathogenic variants in the gene that produces the protein arylsulphatase A. As a result, this protein was deficient in their body. Blood stem cells were removed from trial participants. A normal arylsulphatase A gene and another gene that boosts the production of arylsulphatase A were added to the stem cells. The stem cells were then reintroduced into the participants. Participants who started this trial before the onset of symptoms, ended up with no symptoms or just mild symptoms.

Gene therapy can also be used to grow normal tissue from skin cells. Scientists at the University of Modena in Italy used gene therapy on stem cells to treat a child with epidermolysis bullosa. Epidermolysis bullosa is a genetic condition that can cause severe blisters. The child who was treated had blisters over 80% of his body. Skin stem cells from the child were modified so that they had a normal epidermolysis bullosa gene. These cells were grown into skin tissue and grafted onto the child. This resulted in normal skin tissue that did not blister.

In addition to fixing genetic disease, gene therapy using stem cells can be used to produce better cells. For example, researchers at Harvard University are researching modifying stem cells so that they can produce insulin for people with Type 1 diabetes. Researchers have also potentially cured a man with HIV by transplanting donor cells with a gene variant in the CCR5 receptor. This variant prevents HIV from gaining access to cells. Researchers are looking to replicate this by creating pluripotent stem cells which have a variant in the CCR5 receptor.

Testing new drugs for safety and effectiveness

Scientists can use certain types of stem cells to test whether drugs are safe and effective before testing them

QUESTIONS TO ASK YOUR DOCTOR

- Would stem cell treatment help treat my disease?
- Are there any stem cell clinical trials available for my disease?
- What are the risks of this trial?

directly on people. Researchers also use stem cells to create tissue that potential medications can be tested on. In order for the testing to be accurate, the cells and tissue need to have similar properties to the cells that will eventually be targeted by the drug.

Cord blood banking and donation

Cord blood from the umbilical cord is rich in stem cells. These cells are capable of transforming into many different cells types. These stem cells can be used for research or to treat disease. Some parents store cord blood in case their children eventually need treatment that requires stem cells. Others donate the cord blood so that it can be used in research or to help treat disease in others. There are both public and private cord blood banks that will store cord blood.

Controversies in stem cell research

Some people are concerned about the ethics of using stem cells from human embryos in research. The NIH developed guidelines for stem cell research in 2009. These guidelines determine how stem cells may be used in research and how they may be donated. They also state that stem cells from embryos can only be used when the embryo is no longer needed and the donor has agreed to the donation.

Although adult stem cells can replace embryonic stem cells in some situations, they cannot always be used. They are not as versatile and stable as embryonic stem cells. They cannot currently be manipulated to create all cell types, which limits their use in treatment of diseases. Adult stem cells also are more likely to have genetic variants due to factors like environmental exposure. These variants could cause problems when transplanted into a recipient.

Challenges in stem cell research

One of the biggest risks of using pluripotent stem cells to treat disease is that they can form tumors after transplantation. This is because the methods that create pluripotent cells can result in genetic variants that can

lead to cancer. Researchers are focused on strategies to reduce this risk.

Immune rejection of stem cells is also a risk. This risk is greatest if donor cells are used. Using pluripotent cells derived from the patient reduces, but does not eliminate, the risk of an immune response. In some cases this is due to the viral components that are often used in the development of pluripotent cells. These viral components can trigger an immune response. Even pluripotent cells developed without viruses can trigger a mild immune response due to modifications that can happen in the transformation to pluripotent stem cells.

Studies have found that rare genetic variants in healthy donors may be passed on to recipients undergoing cancer therapy. Drugs designed to prevent an immune reaction in the recipient, can allow the cells with the rare variant to replicate and cause health problems such as other cancers and heart disease.

Stem cells are not immortal and have a limited lifespan. Some have a lifespan of months while others have a lifespan of years. This means that stem cell treatments may need to be repeated in some cases. Also as these stem cells age, they are less able to repair tissues and may become more susceptible to developing cancer.

Steroid-resistant nephrotic syndrome type 2/Galloway-Mowat syndrome

Definition

Steroid-resistant nephrotic syndrome (SRNS) type 2 and Galloway-Mowat syndrome (GMS) are rare congenital nephrotic syndromes inherited in an autosomal recessive pattern and characterized by severe proteinuria, hypoproteinemia, and edema manifesting shortly after birth. Galloway-Mowat syndrome, named for the two Scottish physicians who reported on a family with two children affected by the syndrome in 1968, includes abnormalities of the central nervous system and digestive tract as well as loss of kidney function. Its alternate name is microcephaly-hiatal hernia-nephrotic syndrome. SRNS type 2 is also called nephrotic syndrome 2, hereditary nephrotic syndrome, and nephrotic syndrome, idiopathic, steroid-resistant. Although both disorders are inherited in the same pattern, they are caused by mutations in two different genes: the *NPHS2* gene on chromosome 1 in SRNS type 2 and the *WDR73* gene on chromosome 15 in Galloway-Mowat syndrome.

Description

SRNS type 2 is characterized by childhood-onset indications of disturbed kidney function: large amounts of protein in the urine (proteinuria), high levels of albumin in the urine that may be visible as whitish foam (albuminuria), low levels of protein in the blood

KEY TERMS

Albuminuria—Abnormally high levels of albumin (the most abundant protein in blood) in the urine. Albuminuria may be visible as white foam in the urine.

Bowman's capsule—A cup-shaped sac that surrounds the glomerulus in the kidney and receives the fluid (filtrate) from the blood filtered by the glomerulus.

Cerebellum—A portion of the brain consisting of two cerebellar hemispheres connected by a narrow vermis. The cerebellum is involved in control of skeletal muscles and plays an important role in the coordination of voluntary muscle movement.

Edema—Abnormal accumulation of fluid beneath the skin and within body cavities. Pitting edema refers to the persistence of a pit or indentation that remains after the examiner releases finger pressure on the patient's skin.

End-stage renal disease (ESRD)—A potentially fatal condition that occurs when the kidneys can no longer effectively filter urine and excrete waste products from the body.

Focal segmental glomerulosclerosis (FSGS)—Formation of scar tissue in the filtering unit of the kidney. "Focal" means that only some of the glomeruli are affected; "segmental" means that only a segment or section of an affected glomerulus is damaged.

Glomerulus—A structure in the kidney composed of blood vessels that are actively involved in the filtration of the blood.

Hiatal hernia—A structural defect in the digestive tract in which the upper part of the stomach protrudes (herniates) through an opening or weak area in the diaphragm into the chest.

Hyperreflexia—Having overactive or overresponsive reflexes.

Hypoalbuminemia—An abnormally low level of albumin in the blood.

Hypotonia—Low or poor muscle tone, resulting in floppy limbs.

Loss-of-function mutation—Any mutation that causes a gene to lose its ability to encode a protein either partially or completely.

Microcephaly—Abnormal smallness of the head; it is often associated with intellectual disability.

Nephrotic syndrome—A kidney disorder characterized by high levels of protein in the urine, low levels of albumin in the blood, and edema (abnormal accumulation of fluid in the body). It may be caused by genetic mutations, infections, certain medications, or such other disorders as diabetes and cancer.

Podocytes—Specialized cells in the Bowman's capsule of the kidney that wrap around the capillaries in the glomerulus and serve to prevent large protein molecules from passing into the urine while allowing water and small molecules like salt to pass through.

Proteinuria—An abnormally high level of protein in the urine, defined as higher than 3.5 grams per day in adults or higher than 40 mg/m² per hour in children.

(hypoproteinemia), high levels of cholesterol and lipids (fats) in the blood, susceptibility to infections, and retention of fluid in the body (edema). The edema may be severe enough to show pitting (persistence of a dent or pit in the fluid-swollen skin after the doctor removes finger pressure on the skin). The hallmark of SRNS type 2 is that unlike other forms of nephrotic syndrome, it does not respond to treatment with steroid medications, the basic form of therapy for nephrotic syndrome. SRNS type 2 usually progresses to end-stage renal disease (ESRD).

GWS is evident at birth by congenital abnormalities of the infant's skull and abdomen. The head is unusually small (microcephaly), and the facial features may be malformed. The child may also have abnormalities of the brain tissue itself, such as the absence of the inner layer of the cerebellum, abnormally small folds in the outer

layer of brain tissue (microgyria), and the absence or partial lack of myelin (a fatty substance that facilitates the transmission of electrical impulses through the nervous system by serving as an insulator) in the cerebrum and brain stem.

In addition to the craniofacial deformities and neurological abnormalities, the infant with GMS usually has a hiatal hernia—a condition in which part of the stomach protrudes (herniates) through an abnormal opening in the diaphragm into the chest. Other symptoms may include poor muscle tone (hypotonia), abnormally strong reflexes (hyperreflexia), seizures, developmental delays, and intellectual disability. Abnormalities in the kidneys, such as the formation of scar tissue in some of the glomeruli of the kidneys (focal glomerulosclerosis) or the formation of cysts within the kidney tissue, lead to the

same symptoms of nephrotic syndrome as are found in SRNS type 2: proteinuria, albuminuria, and edema. These renal symptoms may become evident shortly after the child's birth, or they may not appear until he or she is two to three years old.

Genetic profile

Both syndromes are inherited in an autosomal recessive pattern, which means that the offspring needs to inherit two copies of the mutated gene—one from each parent—in order to develop the symptoms of the disorder. SRNS type 2 is caused by a mutation in the *NPHS2* gene on the long arm of chromosome 1 at 1q25. This gene codes for a protein called podocin, which is critical in maintaining the integrity of podocytes, specialized cells in the Bowman's capsule of the kidney that cover the basement membrane of each glomerulus and prevent the passage of albumin and other large protein molecules into the urine. Mutations in the *NPHS2* gene lead to weaknesses in the podocytes and consequent leakage of large amounts of albumin, immunoglobulins, and other proteins into the patient's urine. It is the loss of immunoglobulins from the blood that results in the patient's increased susceptibility to infections. As the level of albumin in the blood drops, fluid that is normally retained in the blood begins to accumulate in body tissues instead, resulting in the edema that marks nephrotic syndrome. Eventually, scarring (focal segmental glomerulosclerosis) may occur in some of the glomeruli, thus accelerating loss of kidney function.

An international team of researchers reported in early 2015 that recessive mutations in the *CRB2* gene on the long arm of chromosome 9 at 9q33.3 are also associated with SRNS type 2. Like *NPHS2*, this gene also appears to be essential to the normal functioning of podocytes and the prevention of loss of protein in the urine.

GWS is caused by loss-of-function mutations in the *WDR73* gene on the long arm of chromosome 15 at 15q25.2. This gene encodes a protein that contains multiple WD40 repeats, which are structural patterns that contain between 40 and 60 amino acids. The function of the protein encoded by the *WDR73* gene was unknown as of 2015, but it appears to be important in prolonging cell survival and maintaining cell structure. The protein is known to be expressed in embryonic kidney tissue as well as in the cerebral cortex and the hippocampus in the brain, which explains why mutations in the *WDR73* gene result in abnormalities of the central nervous system, as well as the kidneys.

Demographics

Both disorders are rare. The prevalence of SRNS type 2 in the general population was unknown as of

2015, but it has been reported in consanguineous families in Turkey and elsewhere, as well as in families in the United Kingdom, Hungary, Israel, Brazil, Italy, France, and Germany.

Prior to late 2014, only about 20 cases of GWS had been reported in the medical literature since the disorder was first identified in 1968. In 2014, a group of researchers in Pennsylvania and Ohio reported on a group of 30 children from various Amish families in the eastern United States who were diagnosed with GWS. The Old Order Amish have a high rate of consanguineous marriages, which explains the increased risk of autosomal recessive genetic disorders among them. GWS has also been identified in Turkish and Moroccan families that allowed marriage between first cousins.

As far as is known, both disorders affect males and females equally and may appear in members of all races and ethnic groups.

Signs and symptoms

The signs and symptoms of SRNS type 2 may appear shortly after birth or not until early childhood, but symptoms typically progress rapidly to end-stage renal disease. Although children with SRNS type 2 do not have the craniofacial abnormalities found in GWS, their loss of kidney function will usually be apparent in the form of edema, abnormally high blood pressure readings, high levels of blood cholesterol, frequent infections, and severe proteinuria on urine tests.

The signs and symptoms of GWS may appear at birth in the form of low birth weight and visible craniofacial abnormalities that include a sloping forehead; a small midface; an unusually small jaw; large, low-set, or floppy ears; cataracts in the eyes; drooping eyelids (ptosis); clenched hands with unusually slender fingers; and hypotonia. Repeated vomiting in early infancy and failure to thrive due to the loss of nutrients may lead to suspicion of hiatal hernia. Delayed motor development, seizures, and intellectual disability are usually apparent by two to three years of age.

Diagnosis

SRNS type 2 is suspected when the child is evaluated for proteinuria, edema, high levels of blood cholesterol, high blood pressure, and other signs of nephrotic syndrome but fails to respond to corticosteroid therapy. A kidney biopsy may be done to look for evidence of scarring in the glomeruli, but the definitive diagnosis is provided by molecular genetic testing for mutations in the *NPHS2* gene.

QUESTIONS TO ASK YOUR DOCTOR

- Have you ever treated a patient with either of these rare congenital nephrotic syndromes?
- If so, did the patient obtain a kidney transplant?
- What treatment would you recommend for the neurological symptoms of Galloway-Mowat syndrome?
- Do you think that gene therapy may offer a potential cure for these disorders?

GMS is suspected at birth on the basis of visible craniofacial abnormalities, while the presence of a hiatal hernia can be confirmed by x-ray imaging. Failure to sit up or walk on the normal timetable, seizures, and intellectual disability will usually become apparent after the first year of life. Loss of kidney function will be evident in the passage of foamy urine, abnormal results on urine tests, and pitting edema in the child's skin. A kidney biopsy may be performed to look for the presence of scar tissue (focal sectional glomerulonephrosis) or cysts in some of the glomeruli of the kidneys. The definitive diagnosis of GMS is provided by molecular genetic testing for mutations in the *WDR73* gene.

Treatment and management

The only curative treatment for either of these autosomal recessive congenital nephrotic syndromes is kidney transplantation. Low-sodium and low-protein diets may be recommended, along with diuretics to control the edema and antibiotics to manage infections, but these measures will not affect the underlying cause of the loss of kidney function. Children with GMS who develop seizures may be given anticonvulsant drugs, but the choice of these drugs and their dosage must be decided on an individual basis, as some antiseizure drugs may interact with other medications given to treat GMS.

Children with SRNS type 2 may be given angiotensin-converting-enzyme (ACE) inhibitors to lower blood pressure, as well as diuretics to reduce edema and antibiotics to treat infections. As loss of kidney function progresses, however, patients with SRNS type 2 will require hemodialysis or kidney transplantation. Some patients develop a recurrence of the disorder even after kidney transplantation.

Prognosis

The prognosis of SRNS type 2 is poor. With careful management, some patients can live into their early 20s, but most patients die during the first decade of life.

The prognosis of GMS is also poor; most affected children die within the first ten years of life of end-stage renal disease. The oldest known patient with the disorder died at age 28.

Rebecca J. Frey, PhD

Stickler syndrome

Definition

Stickler syndrome is a disorder caused by a genetic malfunction in the tissue that connects bones, heart, eyes, and ears.

Description

Stickler syndrome, also known as hereditary arthropathopathy, is a multisystem disorder that can affect

the eyes and ears, skeleton and joints, and craniofacies. Symptoms may include myopia, cataracts, and retinal detachment; hearing loss that is both conductive and sensorineural; midfacial underdevelopment and cleft palate; and mild spondyloepiphyseal dysplasia and/or arthritis. The collection of specific symptoms that make up the syndrome were first documented by Gunnar B. Stickler, et al., in a 1965 paper published in *Mayo Clinic Proceedings* titled “Hereditary Progressive Arthro-Ophthalmopathy.” The paper associated the syndrome’s sight deterioration and joint changes. Subsequent research has redefined Stickler syndrome to include other symptoms.

Genetic profile

Stickler syndrome is associated with mutations in three genes: *COL2A1* (chromosomal locus 12q13), *COL11A1* (chromosomal locus 1p21), and *COL11A2* (chromosomal locus 6p21). It is inherited in an autosomal dominant manner where the majority of individuals with Stickler syndrome inherit the abnormal allele from one parent. The prevalence of new gene mutations that cause Stickler syndrome is unknown. Individuals with Stickler syndrome have a 50% chance of passing on the abnormal gene to each offspring.

The syndrome can manifest itself differently within families. If the molecular genetic basis of Stickler syndrome has been established, molecular genetic testing can be used for clarification of each family member’s genetic status and for prenatal testing.

A majority of cases are attributed to *COL2A1* mutations, all of which are known to cause Stickler syndrome as a result in the formation of a premature termination codon within the type-II collagen gene. Mutations in *COL11A1* have only recently been described and *COL11A2* mutations have been identified only in patients lacking ocular findings.

Although the syndrome is associated with mutations in the *COL2A1*, *COL11A1*, and *COL11A2* genes, no linkage to any of these three known loci can be established in some rare cases with clinical findings consistent with Stickler syndrome. It is presumed that other, as yet unidentified, gene mutations also account for Stickler syndrome.

Genetically related disorders

There are a number of other phenotypes associated with mutations in *COL2A1*. Achondrogenesis type I is a fatal disorder characterized by absence of bone formation in the vertebral column, sacrum, and pubic bones, by the shortening of the limbs and trunk, and by a prominent abdomen. Hypochondrogenesis is a milder variant of achondrogenesis. Spondyloepiphyseal dysplasia congenita,

a disorder with skeletal changes more severe than in Stickler syndrome, manifests in significant short stature, flat facial profile, myopia, and vitreoretinal degeneration. Spondyloepimetaphyseal dysplasia type Strudwick is another skeletal disorder that manifests in severe short stature with severe protrusion of the sternum and scoliosis, cleft palate, and retinal detachment. A distinctive radiographic finding is irregular sclerotic changes, described as dappled, which are created by alternating zones of osteosclerosis and osteopenia in the metaphyses (ends) of the long bones. Spondyloperipheral dysplasia is a rare condition characterized by short stature and radiographic changes consistent with a spondyloepiphyseal dysplasia and brachydactyly. Kniest dysplasia is a disorder that manifests in disproportionate short stature, flat facial profile, myopia and vitreoretinal degeneration, cleft palate, backward and lateral curvature of the spine, and a variety of radiographic changes.

Other phenotypes associated with mutations in *COL11A1* include Marshall syndrome, which manifests in ocular hypertelorism, hypoplasia of the maxilla and nasal bones, flat nasal bridge, and small upturned nasal tip. Unlike Stickler syndrome, the flat facial profile of Marshall syndrome is usually evident into adulthood. Manifestations include hypoplasia of the nasal sinuses and a thickened calvarium. Ocular manifestations include high myopia, fluid vitreous humor, and early-onset cataracts. Sensorineural hearing loss is common and sometimes progressive. Cleft palate is seen both as an isolated occurrence and as part of the Pierre-Robin sequence (micrognathia, cleft palate, and glossoptosis). Other manifestations include short stature, early-onset arthritis, and skin manifestations that may include mild hypotrichosis and hypohidrosis.

Phenotypes associated with mutations in *COL11A2* include autosomal recessive oto-spondylometaphyseal dysplasia, a disorder characterized by flat facial profile, cleft palate, and severe hearing loss. Anocular Stickler syndrome caused by *COL11A2* mutations is similar to this disorder. Weissenbach-Zweymuller syndrome has been characterized as a neonatal form of Stickler syndrome but it is a separate entity from Stickler syndrome. Symptoms include midface hypoplasia with a flat nasal bridge, small upturned nasal tip, micrognathia, sensorineural hearing loss, and rhizomelic limb shortening. Radiographic findings include vertebral coronal clefts and dumbbell-shaped femora and humeri. Catch-up growth after age two or three is common and the skeletal findings become less apparent in later years.

Demographics

No studies have been done to determine Stickler syndrome prevalence. An approximate incidence of Stickler

syndrome among newborns is estimated based on data on the incidence of Pierre-Robin sequence in newborns. One in 10,000 newborns has Pierre-Robin sequence, and 35% of these newborns subsequently develop signs or symptoms of Stickler syndrome. These data suggest that the incidence of Stickler syndrome among neonates is approximately 1 in 7,500.

Signs and symptoms

Stickler syndrome may affect the eyes and ears, skeleton and joints, and craniofacial characteristics. It may also be associated with coronary complications.

Ocular symptoms

Nearsightedness is a common symptom of Stickler syndrome. High myopia is detectable in newborns. Common problems also include astigmatism and cataracts, and risk of retinal detachment is higher than normal. Abnormalities of the vitreous humor, the colorless, transparent jelly that fills the eyeball, are also observed. Type 1, the more common vitreous abnormality, is characterized by a persistence of a vestigial vitreous gel in the space behind the lens, and is bordered by a folded membrane. Sparse and irregularly thickened bundles throughout the vitreous cavity characterize type 2, which is much less common. These vitreous abnormalities can cause sight deterioration.

Auditory symptoms

Hearing impairment is common and some degree of sensorineural hearing loss is found in 40% of patients. The degree of hearing impairment is variable and may be progressive. Typically the impairment is in the high tone frequency and is often subtle. Conductive hearing loss is also possible. It is known that the impairment is related to the expression of type II and IX collagen in the inner ear, but the exact mechanism for it is unclear. Hearing impairment may be secondary to the recurrent ear infections often associated with cleft palate, or it may be secondary to a disorder of the ossicles of the middle ear.

Skeletal symptoms

Skeletal manifestations include short stature relative to unaffected siblings, early-onset arthritis, and abnormalities at ends of long bones and vertebrae. Radiographic findings are consistent with mild spondyloepiphyseal dysplasia. Some individuals have a physique similar to Marfan syndrome, but without tall stature. Young patients may exhibit joint laxity but it diminishes or even resolves completely with age. Early-onset arthritis is common and generally mild, mostly resulting in joint stiffness. Arthritis

KEY TERMS

Cleft palate—A congenital malformation in which there is an abnormal opening in the roof of the mouth that allows the nasal passages and the mouth to be improperly connected.

Dysplasia—The abnormal growth or development of a tissue or organ.

Glossoptosis—Downward displacement or retraction of the tongue.

Micrognathia—Small lower jaw with recession of lower chin.

Mitral valve prolapse—A heart defect in which one of the valves of the heart (which normally controls blood flow) becomes floppy. Mitral valve prolapse may be detected as a heart murmur but there are usually no symptoms.

Otitis media—Inflammation of the middle ear, often due to fluid accumulation secondary to an infection.

Phenotype—The physical expression of an individual's genes.

Spondyloepiphyseal dysplasia—Abnormality of the vertebra and epiphyseal centers that causes a short trunk.

is sometimes severe, leading to joint replacement as early as the third or fourth decade.

Craniofacial findings

Several facial features are common with Stickler syndrome. A flat facial profile referred to as a “scooped-out” face results from underdevelopment of the maxilla and nasal bridge, which can cause telecanthus and epicanthal folds. Flat cheeks, flat nasal bridge, small upper jaw, pronounced upper lip groove, small lower jaw, and palate abnormalities are possible, all in varying degrees. The nasal tip may be small and upturned, making the groove in the middle of the upper lip appear long. Micrognathia is common and may compromise the upper airway, necessitating tracheostomy. Midfacial hypoplasia is most pronounced in infants and young children, and older individuals may have a normal facial profile.

Coronary findings

Mitral valve prolapse may be associated with Stickler syndrome, but studies are still inconclusive about the connection.

Diagnosis

Stickler is believed to be a common syndrome in the United States and Europe, but only a fraction of cases are diagnosed since most patients have minor symptoms. Misdiagnosis may also occur because symptoms are not correlated as having a single cause. More than half of patients with Stickler syndrome are originally misdiagnosed, according to one study.

While the diagnosis of Stickler syndrome is clinically based, clinical diagnostic criteria have not been established. Patients usually do not have all symptoms attributed to Stickler syndrome. The disorder should be considered in individuals with clinical findings in two or more of the following categories:

- **Ophthalmologic.** Congenital or early-onset cataract, myopia greater than -3 diopters, congenital vitreous anomaly, and rhegmatogenous retinal detachment. Normal newborns are typically hyperopic ($+1$ diopter or greater), and so any degree of myopia in an at-risk newborn, such as one with Pierre-Robin sequence or an affected parent, is suggestive of the diagnosis of Stickler syndrome. Less common ophthalmological symptoms include paravascular pigmented lattice degeneration and cataracts.
- **Craniofacial.** Midface hypoplasia, depressed nasal bridge in childhood, anteverted nares (tipped or bent nasal cavity openings), split uvula, cleft hard palate, micrognathia, and Pierre-Robin sequence.
- **Audiologic.** Sensorineural hearing loss.
- **Joint.** Hypermobility, mild spondyloepiphyseal dysplasia, and precocious osteoarthritis.

It is appropriate to evaluate at-risk family members with a medical history and physical examination and ophthalmologic, audiologic, and radiographic assessments. Childhood photographs may be helpful in the evaluation of adults since craniofacial findings may become less distinctive with age.

Molecular genetic testing

Mutation analysis for *COL2A1*, *COL11A1*, and *COL11A2* is available. Detection is performed by mutation scanning of the coding sequences. Stickler syndrome has been associated with stop mutations in *COL2A1* and with missense and splicing mutations in all of the three genes. Because the meaning of a specific missense mutation within the gene coding sequence may not be clear, mutation detection in a parent is not advised without strong clinical support for the diagnosis.

Clinical findings can influence the order for testing the three genes. In patients with ocular findings, including type 1 congenital vitreous abnormality and mild

QUESTIONS TO ASK YOUR DOCTOR

- What is the genetic basis for Stickler syndrome?
- What tests or other criteria are used to diagnose Stickler syndrome?
- What treatments are available for this condition, and how effective are these treatments?
- What provisions should a family make for a child who has been diagnosed with Stickler syndrome to provide the best medical and emotional care at home?

hearing loss, *COL2A1* may be tested first. In patients with typical ocular findings including type 2 congenital vitreous anomaly and significant hearing loss, *COL11A1* may be tested first. In patients with hearing loss and craniofacial and joint manifestations but without ocular findings, *COL11A2* may be tested first.

Prenatal testing

Before considering prenatal testing, its availability must be confirmed and prior testing of family members is usually necessary. Prenatal molecular genetic testing is not usually offered in the absence of a known disease-causing mutation in a parent. For fetuses at 50% risk for Stickler syndrome, a number of options for prenatal testing may exist. If an affected parent has a mutation in the gene *COL2A1* or *COL11A1*, molecular genetic testing may be performed on cells obtained by chorionic villus sampling at 10–12 weeks gestation or amniocentesis at 16–18 weeks gestation. Alternatively, or in conjunction with molecular genetic testing, ultrasound examination can be performed at 19–20 weeks gestation to detect cleft palate. For fetuses with no known family history of Stickler syndrome in which cleft palate is detected, a three-generation pedigree may be obtained, and relatives who have findings suggestive of Stickler syndrome should be evaluated.

Treatment and management

Individuals diagnosed with Stickler syndrome, and individuals in whom the diagnosis cannot be excluded, should be followed for potential complications.

Evaluation by an ophthalmologist familiar with the ocular manifestations of Stickler syndrome is recommended. Individuals with known ocular complications may prefer to be followed by a vitreoretinal specialist. Patients should avoid activities that may lead to traumatic

retinal detachment, such as contact sports. Patients should be advised of the symptoms associated with a retinal detachment and the need for immediate evaluation and treatment when such symptoms occur. Individuals from families with Stickler syndrome and a known *COL2A1* or *COL11A1* mutation who have not inherited the mutant allele do not need close ophthalmologic evaluation.

A baseline audiogram to test hearing should be performed when the diagnosis of Stickler syndrome is suspected. Follow-up audiologic evaluations are recommended in affected persons since hearing loss can be progressive.

Radiological examination may detect signs of mild spondyloepiphyseal dysplasia. Treatment is symptomatic, and includes over-the-counter anti-inflammatory medications before and after physical activity. No preventive therapies currently exist to minimize joint damage in affected individuals. In an effort to delay the onset of arthropathy, physicians may recommend avoiding physical activities that involve high impact to the joints, but no data support this recommendation.

Infants with Pierre-Robin sequence need immediate attention from otolaryngology and pediatric critical care specialists. Evaluation and management in a comprehensive craniofacial clinic that provides all the necessary services, including otolaryngology, plastic surgery, oral and maxillofacial surgery, pediatric dentistry, and orthodontics, is recommended. Tracheostomy may be required, which involves placing a tube in the neck to facilitate breathing.

Middle ear infections (otitis media) may be a recurrent problem secondary to the palatal abnormalities, and ear tubes may be required. Micrognathia (small jaw) tends to become less prominent over time in most patients, allowing for removal of the tracheostomy. In some patients, however, significant micrognathia persists and causes orthodontic problems. In these patients, a mandibular advancement procedure may be required to correct jaw misalignment.

Cardiac care is recommended if complaints suggestive of mitral valve prolapse, such as episodic tachycardia and chest pain, are present. While the prevalence of mitral valve prolapse in Stickler syndrome is unclear, all affected individuals should be screened since individuals with this disorder need antibiotic prophylaxis for certain surgical procedures.

Prognosis

Prognosis is good under physician care. It is particularly important to receive regular vision and hearing exams. If retinal detachment is a risk, it may be advisable

to avoid contact sports. Some craniofacial symptoms may improve with age.

Sturge-Weber syndrome

Definition

Sturge-Weber syndrome (SWS) is a condition involving specific brain changes that often cause seizures and mental delays. It also includes port wine-colored birthmarks (or "port-wine stains"), usually found on the face.

Description

The brain finding in SWS is leptomeningeal angioma, which is a swelling of the tissue surrounding the brain and spinal cord. These angiomas cause seizures in

approximately 90% of people with SWS. A large number of affected individuals are also mentally delayed.

Port-wine stains are present at birth. They can be quite large and are typically found on the face near the eyes or on the eyelids. Vision problems are common, especially if a port-wine stain covers the eyes. These vision problems can include glaucoma and vision loss.

Facial features, such as port-wine stains, can be very challenging for individuals with SWS. These birthmarks can increase in size with time, and this may be particularly emotionally distressing for the individuals, as well as their parents. A state of unhappiness about this is more common during middle childhood and later than it is at younger ages.

Genetic profile

The genetics behind Sturge-Weber syndrome are still unknown. Interestingly, in other genetic conditions involving changes in the skin and brain (such as neurofibromatosis and tuberous sclerosis) the genetic causes are well described. It is known that most people with SWS are the only ones in their family with the condition; there is usually not a strong family history of the disease. However, the gene known to cause SWS is still not known.

MRI scan of a brain with Sturge-Weber syndrome. The front of the brain is at the top. Red-colored areas indicate fluid-filled ventricles. The blue area is where the brain has become calcified. (Mehau Kulyk/Science Source)

KEY TERMS

Calcification—A process in which tissue becomes hardened due to calcium deposits.

Choroid—A vascular membrane that covers the back of the eye between the retina and the sclera and serves to nourish the retina and absorb scattered light.

Computed tomography (CT) scan—An imaging procedure that produces a three-dimensional picture of organs or structures inside the body, such as the brain.

Glaucoma—An increase in the fluid eye pressure, eventually leading to damage of the optic nerve and ongoing visual loss.

Leptomeningeal angioma—A swelling of the tissue or membrane surrounding the brain and spinal cord, which can enlarge with time.

Magnetic resonance imaging (MRI)—A technique that employs magnetic fields and radio waves to create detailed images of internal body structures and organs, including the brain.

Port-wine stain—Dark-red birthmarks seen on the skin, named after the color of the dessert wine.

Sclera—The tough white membrane that forms the outer layer of the eyeball.

For now, SWS is thought to be caused by a random, sporadic event.

Demographics

Sturge-Weber syndrome is a sporadic disease that is found throughout the world, affecting males and females equally. The total number of people with Sturge-Weber syndrome is not known, but estimates range between 1 in 400,000 to 1 in 40,000.

Signs and symptoms

People with SWS may have a larger head circumference (measurement around the head) than usual. Leptomeningeal angiomas can progress with time. They usually only occur on one side of the brain, but can exist on both sides in up to 30% of people with SWS. The angiomas can also cause great changes within the brain's white matter. Generalized wasting, or regression, of portions of the brain can result from large angiomas. Calcification of the portions of the brain underlying the angiomas can also occur. The larger and more involved the angiomas are, the greater the expected amount of

mental delays in the individual. Seizures are common in SWS, and they can often begin in very early childhood. Occasionally, slight paralysis affecting one side of the body may occur.

Port-wine stains are actually capillaries (blood vessels) that reach the skin's surface and grow larger than usual. As mentioned earlier, the birthmarks mostly occur near the eyes; they often occur only on one side of the face. Though they can increase in size over time, port-wine stains cause no direct health problems for the person with SWS.

Vision loss and other complications are common in SWS. The choroid of the eye can swell, and this may lead to increased pressure within the eye in 33%–50% of people with SWS. Glaucoma is another common vision problem seen in SWS, and is more often seen when a person has a port-wine stain that is near or touches the eye.

In a 2000 study about the psychological functioning of children with SWS it was noted that parents and teachers report a higher incidence of social problems, emotional distress, and problems with compliance in these individuals. Taking the mental delays into account, behaviors associated with attention-deficit hyperactivity disorder (ADHD) were noted; as it turns out, about 22% of people with SWS are eventually diagnosed with ADHD.

Diagnosis

Because no genetic testing is available for Sturge-Weber syndrome, all diagnoses are made through a careful physical examination and study of a person's medical history.

Port-wine stains are present at birth, and seizures may occur in early childhood. If an individual has both of these features, SWS should be suspected. A brain MRI or CT scan can often reveal a leptomeningeal angioma, brain calcifications, as well as any other associated white matter changes.

Treatment and management

Treatment of seizures in SWS by antiepileptic medications is often an effective way to control them. In the rare occasion that an aggressive seizure medication therapy is not effective, surgery may be necessary. The general goal of the surgery is to remove the portion of the brain that is causing the seizures, while keeping the normal brain tissue intact. Though most patients with SWS only have brain surgery as a final attempt to treat seizures, some physicians favor earlier surgery because this may prevent some irreversible damage to the brain (caused by the angiomas).

QUESTIONS TO ASK YOUR DOCTOR

- What is the status of current research on the genetic basis of Sturge-Weber syndrome?
- How common is Sturge-Weber syndrome in the general population and in any populations at special risk?
- Should individuals with Sturge-Weber be subject to regular medical monitoring and, if so, what kind of tests should be conducted?
- Are there sources on the Internet that can provide me with additional information about this disorder?

Standard glaucoma treatment, including medications and surgery, is used to treat people with this complication. This can often reduce the amount of vision loss.

There is no specific treatment for port-wine stains. Because they contain blood vessels, it could disrupt blood flow to remove or alter the birthmarks.

Prognosis

The prognosis for people with SWS is directly related to the amount of brain involvement for the leptomeningeal angiomas. For those individuals with smaller angiomas, prognosis is relatively good, especially if they do not have severe seizures or vision problems.

Super Enhancers (SE)

Definition

Enhancers are short regions of DNA that activate the expression (transcription) of their associated genes. These regions of about 50–1,500 nucleotide base pairs (the building blocks of DNA) bind proteins called transcription factors. The binding of these factors to enhancer sequences promotes the transcription of genes into RNAs, which subsequently may be translated to produce the corresponding proteins. Super enhancers (SEs) are clusters of enhancers that are responsible for determining and maintaining cell types. Variations or mutations (changes) in the DNA sequences of SEs appear to be associated with the development of various diseases, including autoimmune disorders and cancers.

Description

The hundreds of different types of cells in the human body share the same DNA sequence (genome); however, the specific genes that are expressed (transcribed) in the cells determine their cell type or identity. To a large extent, the regulation of this differential gene expression in different types of cells is controlled by enhancers. Enhancers are DNA sequences that are typically a few hundred base pairs in length. These enhancer sequences bind multiple transcription factors and activators and RNA polymerase II, the enzyme that copies (transcribes) the DNA of a gene into RNA that may be translated to produce the protein encoded by the gene. There are approximately one million enhancers in the human genome, of which tens of thousands are estimated to be active in a given cell type. Enhancers are very important, not just for controlling the expression of cell-type-specific genes, but also because many of the variations in DNA sequences that are associated with diseases occur in enhancers.

SEs are also called “stretch enhancers” because they are formed from multiple enhancers that are clustered or “stretched” together by the densely packed binding of proteins, including “master” transcription factors and the

mediator coactivator complex. SEs differ from typical enhancers in important ways:

- They are much larger.
- They are much more densely packed with transcription factors and other proteins that differ from those that bind to typical enhancers.
- They bind very high levels of a complex of proteins called the mediator coactivator complex, which is important for activating gene transcription.
- They are in particularly close proximity to the genes they regulate.
- They promote much more active transcription of their associated genes.
- They are associated with genes that encode cell-type-specific transcription factors—transcription factors that are only active in specific cell types. In contrast, typical enhancer-associated genes tend to be active in many different types of cells.
- They are very susceptible to perturbation that results in the loss of bound proteins and results in changes in gene transcription activity.

SEs are very powerful molecular “switches” that promote high-level expression (transcription) of genes that determine and maintain cell type (cell identity). Scientists can locate SEs in the genomes of specific types of cells by looking for regions of DNA that are open and accessible for the binding of regulatory proteins, rather than tightly coiled and protected by chromosomal proteins called histones. By identifying the transcription factors that bind to SEs in different cell types, researchers can determine which factors control the cell-specific activation of genes that maintain the functions of specific cell types.

In addition to associating with genes that control cell type and cell-type-specific functions, SEs tend to be acquired by genes that encode potential master transcription factors and regulatory RNAs that do not make proteins. SEs bind unusually high amounts of RNA polymerase II and its associated cofactors and chromatin regulators (proteins that make the DNA in chromosomes available for transcription), which are responsible for transcribing enhancer RNAs (eRNAs) from enhancer sequences. These eRNAs may also be involved in gene activation.

Embryonic stem cells (ESCs)

ESCs are cells from the earliest stages of embryonic development and can develop or differentiate into any type of cell in the body. Thus, they are a major focus of scientific investigations. In ESCs, SEs are bound by transcription factors, cofactors, chromatin regulators, and other proteins required for gene transcription. SEs are

associated with genes that define and control cell differentiation. ESC master transcription factors, such as Oct4, Sox2, Nanog, Klf4, and Esrrb, bind to (occupy) enhancers and recruit the mediator coactivator complex to form SEs. Mediator and the master transcription factors recruit RNA polymerase II to transcribe genes that are important for establishing and maintaining the ESC state and for embryonic development. Transcription of the genes that produce the Oct4, Sox2, and Nanog master transcription factor proteins are themselves regulated by SEs.

Although many additional transcription factors occupy both typical enhancers and SEs in ESCs, a 2013 study found that SEs have high levels of various other proteins compared with typical enhancers, including a wide variety of cofactors and chromatin regulators. These are involved in activating genes, modifying histones and nucleosomes (chromosome structures), and looping enhancers to put them into proximity to each other and to the genes that they activate. Differentiation of ESCs into specific cell types is accompanied by changes in the proteins that bind to SEs; this “turns off” or inactivates some SE-associated genes. Reduced levels of Oct4 or mediator in an SE result in a greater loss of the associated gene expression compared to other enhancers. This loss of master transcription factors may be the mechanism by which gene-expression patterns are switched as ESCs differentiate into specific types of cells.

Genetic disorders

Genetic variations (mutations) that are associated with disease are very common in SEs of disease-related cell types. Changes in single nucleotides in the DNA sequence, called single-nucleotide polymorphisms (SNPs), are associated with the development of many diseases and disorders. Many of these disease-associated SNPs are located within SEs of relevant cell types. Because SEs drive the expression of cell-identity genes, it is possible that the altered expression of these genes resulting from mutations in SEs contributes to various diseases.

Autoimmune disorders

Autoimmune disorders are diseases in which immune system cells attack the body’s own proteins rather than foreign proteins and microorganisms that pose a threat. It has been difficult to identify susceptibility genes associated with autoimmune disorders, but enhancers have been suspected of playing a role. In part, this is because many of the mutations that have been identified as associated with autoimmune disorders are not located within DNA that codes for proteins. Because SEs are particularly powerful enhancers of gene transcription that act as genetic

KEY TERMS

Autoimmune disorder—A disorder that occurs when the body’s tissues are attacked by its own immune system, as in RA.

Cytokine—A protein associated with inflammation that, at high levels, may be toxic to nerve cells in the developing brain.

Embryonic stem cells (ESCs)—Cells from early-stage embryos that have the capacity to differentiate into any cell type (pluripotency).

Enhancer—A DNA sequence that binds transcription factors to promote gene activity (transcription).

Mediator coactivator complex—A large protein complex that binds to super enhancers to activate genes.

Oncogene—A gene that allows the uncontrolled division and proliferation of cells that lead to tumor formation and usually to cancer.

Rheumatoid arthritis (RA)—A chronic autoimmune disease marked by inflammation of the membranes surrounding joints.

Single-nucleotide polymorphisms (SNPs)—Single-nucleotide variant (SNV); a variation or point mutation in a single-nucleotide building block of DNA.

T cells—Immune system cells that originate in the thymus gland and are involved in autoimmune disorders.

Transcription factor—A factor that activates the transformation of DNA to RNA (the next step is translation, in which RNA is changed into protein).

switches, researchers have wondered if they could be involved in autoimmunity.

In 2015, a research group headed by John J. O’Shea, scientific director of the National Institute of Arthritis and Musculoskeletal and Skin Diseases, reported the discovery of an SE that appears to be an important regulator of immune system genes and may play a role in autoimmune diseases. O’Shea and his colleagues examined SEs in T cells, a type of immune cell that is an important factor in the autoimmune disease rheumatoid arthritis (RA). RA causes painful swelling and inflammation of the joints. The researchers found that many of the identified mutations in T cells that were known to be associated with RA or other autoimmune diseases were located in SEs. Specifically, SEs were controlling the production of immune system proteins called cytokines and their

receptors, which facilitate communication between T cells and other cells to launch immune responses. When the researchers treated human T cells with tofacitinib, a drug used in the treatment of RA, they discovered that the drug altered the expression of genes that were under the control of SEs, without significantly affecting the expression of genes that were not under SE control. Thus, tofacitinib may exert its anti-RA effects by inhibiting the activity of genes that are being controlled by malfunctioning SEs.

Many autoimmune disorders are believed to be caused by interactions between environmental factors and susceptibility genes. Variations or mutations in the DNA sequences of SEs of such genes are suspected of being involved in at least some autoimmune disorders:

- Type 1 diabetes is caused by the autoimmune destruction of insulin-producing beta cells in the pancreas, a process mediated by T cells. Of the 76 SNPs that have been associated with type 1 diabetes, 67 are in non-protein-coding DNA sequences, especially in the SEs of T helper (Th) cells. Thirteen of the SNPs are in SEs associated with genes that are important for Th cell biology.
- Systemic lupus erythematosus (SLE) is a serious autoimmune disease that can affect the entire body. Of the 72 SNPs that have been associated with SLE, 67 are in non-protein-coding regions, especially in the SEs of a type of immune cell called a B cell, with 22 SNPs in SEs of 16 genes that are important for B cell activity.
- Multiple sclerosis (MS) is an autoimmune disease in which the immune system attacks myelin, the fatty covering of nerve cells that protects the cells and facilitates the transmission of nerve impulses. Damage to myelin from MS interferes with nerve transmission and causes pain, movement difficulties, loss of sensation, and other problems. At least some forms of MS may be associated with mutations or variations in SEs.
- Other autoimmune disorders that may be associated with mutations in SEs include systemic scleroderma, primary biliary cirrhosis, Crohn's disease, Graves' disease, vitiligo, and atrial fibrillation.

The discovery of SNPs in SEs that control the activities of immune system genes that are involved in autoimmune disorders helps explain how susceptibility to these disorders, which often run in families, can be inherited when no mutations have been found in the protein-coding regions of genes that appear to be involved in the disorders.

Alzheimer's disease

Alzheimer's disease is the most common form of dementia. It is characterized by progressive neurodegeneration and loss of cognitive functions. Of the 27 SNPs that have been associated with Alzheimer's disease, five

QUESTIONS TO ASK YOUR DOCTOR

- Could my autoimmune disorder be caused by a mutation in a super enhancer?
- Is genetic testing available for super enhancer mutations?
- Are there targeted drugs available for diseases caused by super enhancers?

occur in SEs in brain tissue. Two of these SNPs are in the SE associated with the *BIN1* gene, whose activity is linked to a risk for developing the disease.

Cancer

Oncogenes are mutated proto-oncogenes that promote cancer development (carcinogenesis). Many important oncogenes in several types of cancer have associated SEs. These SEs are not present in the proto-oncogenes that normally regulate cell growth and development and have not mutated into oncogenes. It appears that acquiring SEs to drive the expression of oncogenes may be an important mechanism in the development of cancer. Cancer cells also have SEs associated with other genes that are important for the growth and pathogenesis of cancer. These SEs are not present in the corresponding noncancerous cells. In fact, a large proportion of genes that have important functions in cancer cell development and pathogenesis appear to have acquired SEs.

DNA translocations (the breakage and rejoining of DNA sequences in different locations), amplifications (increases in the number of copies of DNA sequences), and overexpression of transcription factors appear to account for the acquisition of SEs by cancer cells. For example, multiple myeloma cells often have a translocation that positions a specific SE adjacent to the *MYC* oncogene. Overexpression of the *TAL1* transcription factor in acute lymphoblastic leukemia is also associated with the formation of an SE near the *MYC* oncogene.

Surdicardiac syndrome see **Jervell and Lange-Nielsen syndrome**

SWI/SNF-related autism syndrome

Definition

SWI/SNF-related autism syndrome is a genetic disorder classified as an autism spectrum disorder or ASD. Children with ASDs have difficulty interacting socially with others; have problems with both verbal and nonverbal communication, including delayed speech; and have restricted repetitive patterns of behavior known as stereotypy. Stereotyped behaviors in ASDs include such actions as hand flapping, head-banging, or rocking back and forth.

SWI/SNF-related autism syndrome is also defined as a form of syndromic autism, which means that the disorder has clinical features in addition to the autism itself. SWI/SNF-related autism syndrome is distinguished by mild to severe intellectual disability and malformed facial features. Other names for the syndrome include Helsmoortel-Van der Aa syndrome (HVDAS) and intellectual disability, autosomal dominant, 28 (MRD28).

Description

Children with SWI/SNF-related autism syndrome have many of the same characteristics as children diagnosed with other ASDs; however, they have more severe developmental delays, mild to severe intellectual disabilities, dysmorphic facial features, visual disorders, and

other neuropsychiatric disorders that include obsessive-compulsive disorder, attention deficit hyperactivity disorder, and anxiety disorders.

Genetic profile

SWI/SNF-associated autism syndrome is inherited in an autosomal dominant pattern, which means that only one copy of the mutated gene is necessary for the disorder to appear in a child. The gene associated with the syndrome is the *ADNP* gene on the long arm of chromosome 20 at 20q13.13. This gene has been the subject of interest of a group of researchers at the University of Antwerp in Belgium who formed the ADNP Research Project after the relationship between the *ADNP* gene and the SWI/SNF complex was reported in 2007. The name of the gene stands for “activity-dependent neuroprotective protein,” and deficiencies in the protein that the gene encodes were found to affect the function of the SWI/SNF complex in chromatin remodeling. Mutations in other genes associated with the SWI/SNF complex were linked to two other syndromes characterized by intellectual disability in 2012.

To understand the relationship between the *ADNP* gene, its protein product, and the SWI/SNF chromatin remodeling complex, it is necessary to review the way in which genetic material is packaged inside a cell and the ways in which this packaging can be rearranged to regulate gene expression; that is, to “turn on” or “turn off” specific genes during development or cell reproduction. The term “SWI/SNF” refers to a group of proteins that associate (form a complex) to remodel (rearrange) the way that DNA is packaged inside a cell. The SWI/SNF complex changes the arrangement of nucleosomes, which are the basic units of DNA packaging. A nucleosome consists of eight proteins called histones, with about 147 base pairs of DNA wound around them somewhat like thread or yarn around a spool. The nucleosomes in turn are arranged like beads on a string to form chromatin, which is the genetic material found in the nucleus of a cell. Chromatin is made up of DNA, RNA, and proteins, and it condenses to form chromosomes during the process of cell division.

In addition to functioning as a tumor suppressor in many human cancers, the SWI/SNF protein complex helps to regulate gene expression (“turning on” specific genes) by making the nucleosomes in the chromatin of a cell more accessible to transcription factors. Transcription factors are proteins that control the rate of transcription (copying) of specific segments of DNA into messenger RNA. The *ADNP* gene encodes a protein that is thought to act as a transcription factor. The researchers who reported on the initial group of ten patients theorize that mutations in the *ADNP* gene interfere with the ability of

the SWI/SNF complex to rearrange the nucleosomes in the cell's chromatin correctly, leading to irregularities in gene expression and disruptions in nerve cell formation and reproduction. Abnormalities in the formation of nerve cells would help to explain the intellectual disability and psychiatric disorders found in SWI/SNF-related autism syndrome. While the functions of the ADNP protein are not completely understood, it is thought to stimulate the growth of certain types of tumor cells while inhibiting the growth of others. Thus mutations in this gene may be linked to an increased risk of cancer as well as intellectual disability.

Demographics

It is not yet clear how common SWI/SNF-related autism syndrome may be worldwide because the syndrome was reported only in 2014 and involved a total of 15 patients studied by three groups of researchers. Fourteen of the 15 patients are Europeans from Belgium, the Netherlands, and the United Kingdom, with the remaining patient being a six-year-old girl in the United States. Given this small number of patients, further research will be needed to determine whether SWI/SNF-related autism syndrome is more common in some racial or ethnic groups than others. The disorder is more likely to appear in males, with eight of the first 10 patients identified being boys.

Signs and symptoms

According to the ADNP Research Project, the major features of SWI/SNF-related autism syndrome include the following:

- behaviors characteristic of an ASD, including stereotypy
- intellectual disability ranging from mild (40% of patients) to severe (40%)
- developmental delays apparent in infancy
- hypotonia (poor muscle tone and muscle weakness)
- *de novo* mutation in the *ADNP* gene in 75% of patients
- delayed motor development
- delayed speech development
- delayed growth, short stature, and a tendency to obesity
- facial deformities: prominent forehead, notched eyelids, drooping eyelids (ptosis), short nose, thin upper lip, absence of a philtrum (vertical groove) in the upper lip
- behavioral disorders: obsessive-compulsive disorder, anxiety disorders, attention-deficit hyperactivity disorder
- recurrent infections

Less common signs and symptoms include the following:

- seizures
- high pain threshold

KEY TERMS

Autism spectrum disorders (ASDs)—A general term for a group of neurodevelopmental disorders characterized by difficulties in social interactions, significant abnormalities in speech patterns, and limited but repetitive interests and activities.

Autosomal dominant—A pattern of inheritance in which only one copy of a defective gene on a nonsex chromosome is required for a disease or inherited trait to develop in an individual.

Autosome—One of the 22 chromosomes that are not involved in determining gender (chromosomes 1 through 22 and not the X or Y chromosome).

Chromatin—A complex found in mammalian cells consisting of DNA, protein, and RNA. Chromatin serves to package DNA into a smaller volume that will fit within the cell to prevent damage to DNA and to control DNA replication and gene expression. It condenses to form chromosomes during the process of cell division.

De novo mutation—A genetic mutation that is seen for the first time in the affected person, not inherited from the parents.

Dysmorphic—An abnormal body structure often associated with a genetic disorder.

Histones—Alkaline proteins found in cell nuclei that organize and wrap strands of DNA into units called nucleosomes.

Hypotonia—Low or poor muscle tone, resulting in floppy limbs.

Nucleosome—A basic unit of DNA packaging consisting of a segment of DNA wrapped around eight histone proteins.

Ptosis—Drooping of the upper eyelid.

Stereotypy—A repetitive movement, gesture, or utterance; examples include head banging, rocking, or repeatedly crossing and uncrossing the legs. Stereotypy is found in persons with intellectual disabilities and some forms of schizophrenia as well as autism spectrum disorders.

Syndromic autism—A term used to describe autism that exists in combination with other clinical features, including physical as well as developmental abnormalities.

Transcription factor—A factor that activates the transformation of DNA to RNA (the next step is translation, in which RNA is changed into protein).

QUESTIONS TO ASK YOUR DOCTOR

- How common is syndromic autism in comparison to ASDs that are not associated with a clinical syndrome?
 - Have you ever seen a case of syndromic autism?
 - Should I have my child tested for mutations in specific genes known to be linked to autism?
 - Do you think there is a genetic link between syndromic autism and an increased risk of cancer?
- visual disturbances: farsightedness, cataracts, or astigmatism
 - mood disorders
 - congenital heart defects

Diagnosis

The diagnosis of autism spectrum disorders is made on the basis of clinical symptoms observed in the child in late infancy or early childhood. The Centers for Disease Control and Prevention and the American Academy of Pediatrics recommend that all children should be screened twice, at 18 months of age and again at 24 months. Screening consists of the use of a questionnaire or checklist to evaluate such signs as the child's failure to respond to his or her name, inability to make eye contact, lack of social skills, stereotyped behaviors, failure to learn language skills or loss of language skills previously attained, unusual preoccupation with certain objects or activities, and tendency to become extremely upset when routines or schedules are changed. The standard instrument used by pediatricians and other medical professionals in evaluating children for autism is the *Autism Diagnostic Observation Schedule*, second edition (ADOS-2); there are also checklists for use by parents available on the Autism Speaks website.

Children who are suspected of being at risk of autism on the basis of the ADOS-2 or other checklists are then given a comprehensive follow-up examination by a group of specialists—most often a child psychiatrist, a neurologist, a psychologist, and a speech-language pathologist. Imaging studies are not useful in diagnosing autism, although the child may be given an electroencephalogram to rule out seizure disorder. The child may also have his or her hearing tested to be sure that delayed speech is not the result of impaired hearing.

As of 2015, genetic testing was available for SWI/SNF-related autism syndrome at two laboratories in the United States, one in South Carolina and the other in California.

Treatment and management

There is no cure for SWI/SNF-related autism syndrome or any other form of syndromic autism. Patients are treated with a combination of special education programs, speech therapy, and medications for those with seizure disorder. All treatments are highly individualized. One patient with visual problems was successfully treated with surgery. It is possible that the identification of more patients with SWI/SNF-related autism syndrome combined with long-term follow-up of the patients already identified will yield more specific treatment recommendations.

Prognosis

The prognosis of SWI/SNF-related autism syndrome depends partly on the severity of the child's intellectual disability. Children with relatively mild intellectual disability may be able to care for themselves and live in sheltered residential settings, but most will require full-time care at home or in institutional settings throughout their lives. As far as is known, the syndrome does not affect the patient's life expectancy, but further research will be needed to determine whether mutations in the *ADNP* gene may increase the child's risk of cancer in adult life.

Tangier disease

Definition

Tangier disease is a rare autosomal recessive condition characterized by low levels of high-density lipoprotein cholesterol (HDL-C) in the blood, accumulation of cholesterol in many organs of the body, and an increased risk of arteriosclerosis.

Description

Donald Fredrickson was the first to discover Tangier disease. He described this condition in 1961 in a five-year-old boy from Tangier Island who had large, yellow-orange colored tonsils that were engorged with cholesterol. Subsequent tests on this boy and his sister found that they both had virtually no HDL-C in their bloodstream. Other symptoms of Tangier disease such as an enlarged spleen and liver, eye abnormalities, and neurological abnormalities were later discovered in others affected with this disease.

It was not until 1999 that the gene for Tangier disease, called the *ABCA1* gene, was discovered. This gene is responsible for producing a protein that is involved in the pathway by which HDL removes cholesterol from the cells of the body and transports it to the liver where it is digested and removed from the body.

Cholesterol is transported through the body as part of lipoproteins. Low-density lipoproteins (LDL) and high-density lipoproteins (HDL) are two of the major cholesterol-transporting lipoproteins. Cholesterol attached to LDL (LDL-C) is often called bad cholesterol since it can remain in the bloodstream for a long time, and high levels of LDL-C can increase the risk of clogging of the arteries (arteriosclerosis) and heart disease.

Cholesterol attached to HDL is often called good cholesterol since it does not stay in the bloodstream for a long period of time, and high levels are associated with a low risk of arteriosclerosis.

Research suggests that the ABCA1 protein helps to transport cholesterol found in the cell to the surface of the cell where it joins with a protein called ApoA-1 and forms an HDL-C complex. The HDL-C complex transports the cholesterol to the liver where the cholesterol is digested and removed from the body. This process normally prevents an excess accumulation of cholesterol in the cells of the body and can help to protect against arteriosclerosis.

Genetic profile

Changes in the *ABCA1* gene, such as those found in Tangier disease, cause the gene to produce abnormal ABCA1 protein. The abnormal ABCA1 protein is less able to transport cholesterol to the surface of the cell, which results in an accumulation of cholesterol in the cell. The accumulation of cholesterol in the cells of the body causes most of the symptoms associated with Tangier disease. The decreased efficiency in removing cholesterol from the body can lead to an increased accumulation of cholesterol in the blood vessels, which can lead to a slightly increased risk of arteriosclerosis, and ultimately an increased risk of heart attacks and strokes. The ABCA1 protein defect also results in decreased amounts of cholesterol available on the surface of the cell to bind to ApoA-1 and decreased cholesterol available to form HDL-C. This in turn results in the rapid degradation of ApoA-1 and reduced levels of ApoA-1 and HDL-C in the bloodstream. It also leads to lower levels of LDL-C in the blood.

The *ABCA1* gene is found on chromosome 9. Since we inherit one chromosome 9 from our mother and one chromosome 9 from our father, we also inherit two *ABCA1* genes. People with Tangier disease have inherited one changed *ABCA1* gene from their father and one

KEY TERMS

Anemia—A blood condition in which the level of hemoglobin or the number of red blood cells falls below normal values. Common symptoms include paleness, fatigue, and shortness of breath.

Arteriosclerosis—Hardening of the arteries that often results in decreased ability of blood to flow smoothly.

Autosomal recessive—A pattern of genetic inheritance where two abnormal genes are needed to display the trait or disease.

Biochemical testing—Measuring the amount or activity of a particular enzyme or protein in a sample of blood, urine, or other tissue from the body.

Cholesterol—A fatty-like substance that is obtained from the diet and produced by the liver. Cells require cholesterol for their normal daily functions.

Chromosome—A microscopic thread-like structure found within each cell of the body that consists of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Deoxyribonucleic acid (DNA)—The genetic material in cells that holds the inherited instructions for growth, development, and cellular functioning.

DNA testing—Analysis of DNA (the genetic component of cells) in order to determine changes in genes that may indicate a specific disorder.

Gene—A building block of inheritance, which contains the instructions for the production of a particular protein, and is made up of a molecular

sequence found on a section of DNA. Each gene is found on a precise location on a chromosome.

Hemolytic anemia—Anemia that results from premature destruction and decreased numbers of red blood cells.

High-density lipoprotein (HDL)—A cholesterol-carrying substance that helps remove cholesterol from the cells of the body and deliver it to the liver where it is digested and removed from the body.

Low-density lipoproteins (LDL)—A cholesterol-carrying substance that can remain in the bloodstream for a long period of time.

Lymph node—A bean-sized mass of tissue that is part of the immune system and is found in different areas of the body.

Mucous membrane—Thin, mucous-covered layer of tissue that lines organs such as the intestinal tract.

Prenatal testing—Testing for a disease such as a genetic condition in an unborn baby.

Protein—Important building blocks of the body, composed of amino acids, involved in the formation of body structures and controlling the basic functions of the human body.

Spleen—Organ located in the upper abdominal cavity that filters out old red blood cells and helps fight bacterial infections. Responsible for breaking down spherocytes at a rapid rate.

Thymus gland—An endocrine gland located in the front of the neck that houses and transports T cells, which help to fight infection.

Ureters—Tubes through which urine is transported from the kidneys to the bladder.

changed *ABCA1* gene from their mother, making Tangier disease an autosomal recessive condition.

Parents who have a child with Tangier disease are called carriers, since they each possess one changed *ABCA1* gene and one unchanged *ABCA1* gene. Carriers for Tangier disease do not have any of the symptoms associated with the disease, except for increased levels of HDL-C in their bloodstream and a slightly increased risk of arteriosclerosis. The degree of risk of arteriosclerosis is unknown, and is dependent on other genetic and environmental factors, such as diet. Each child born to parents who are both carriers of Tangier disease has a 25% chance of having Tangier disease, a 50% chance of being

a carrier, and a 25% chance of being neither a carrier nor affected with Tangier disease.

Demographics

Tangier disease is a very rare disorder with less than 100 cases diagnosed worldwide. Tangier disease affects both males and females.

Signs and symptoms

The symptoms of Tangier disease are quite variable but the most common symptoms are enlarged, yellow-colored tonsils, an enlarged spleen, accumulation of

cholesterol in the mucous membranes of the intestines, abnormalities in the nervous system (neuropathy), and an increased risk of arteriosclerosis. Less commonly seen symptoms are an enlarged liver, lymph nodes, and thymus and hemolytic anemia. Cholesterol accumulation has been seen in other organs such as the bone marrow, gall bladder, skin, kidneys, heart valves, ureters, testicles, and the cornea of the eye.

Symptoms involving the tonsils, intestines, and spleen

The unusual appearance of the tonsils is due to an accumulation of cholesterol. Even when the tonsils are removed, small yellow patches at the back of the throat may be evident. The accumulation of cholesterol in the mucous membranes of the intestines results in the appearance of orange-brown spots on the rectum, and can occasionally result in intermittent diarrhea and abdominal pain. The enlargement of the spleen can result in anemia and decreased numbers of certain blood cells called platelets.

Nervous system abnormalities

Cholesterol can accumulate in the nerve cells, which can result in nervous system abnormalities and symptoms such as loss of heat and pain sensation, weakness, increased sweating, burning/prickling sensations, loss of feeling, eye muscle spasms, double vision, drooping eyelids, and decreased strength and reflexes. These symptoms can be mild to severe, and can be temporary or permanent. Most people with Tangier disease have some nervous system dysfunction, but in many cases the symptoms are mild and may be undetectable. Occasionally patients with Tangier disease experience progressive and debilitating nervous system abnormalities.

Arteriosclerosis

Since so few people are known to be affected with Tangier disease it is difficult to precisely predict their risk of developing arteriosclerosis and heart disease. Depending on their age, people with Tangier disease appear to have approximately four to six times increased risk for arteriosclerosis leading to heart disease. People over the age of 30 appear to have a sixfold increased risk. It is possible that Tangier patients are protected from higher risks of arteriosclerosis by lower than average levels of LDL-C in their bloodstream.

Diagnosis

Tangier disease is diagnosed through assessment of clinical symptoms and biochemical testing. A diagnosis of Tangier disease should be considered in anyone with deposits of cholesterol on the cornea, an unexplained enlarged spleen or liver, or neurological abnormalities.

QUESTIONS TO ASK YOUR DOCTOR

- What are the most common signs and symptoms of Tangier disease?
- What are the most serious long-term medical problems with which a person with Tangier disease may have to deal?
- What types of treatment are available for this condition, and what risks are involved with each type of treatment?
- Can you recommend any written material that will provide more information about Tangier disease?

Examination of the throat, tonsils, and rectal mucous membrane should be performed on those suspected to have Tangier disease. Measurements of the total cholesterol—HDL-C, LDL-C, ApoA-1, and triglycerides—should also be performed. Patients with Tangier disease have virtually no HDL-C in their bloodstream and ApoA-1 levels are reduced to 1% – 3% of normal. LDL-C levels are also reduced to approximately 40% of normal and triglyceride levels can be mildly elevated. As of 2001, DNA testing for Tangier disease is not available through clinical laboratories, although DNA testing on a clinical basis should be available in the future. Some laboratories may identify *ABCA1* gene changes in patients as part of their research. Prenatal testing is only available if *ABCA1* gene changes are identified in the parents.

Treatment and management

There is no treatment for Tangier disease, and treatment of decreased HDL-C with medication is usually ineffective. Occasionally, organs such as the spleen and tonsils are removed because of extensive accumulation of cholesterol. Arteriosclerosis may be treated through angioplasty or bypass surgery. Angioplasty involves inserting a small, hollow tube called a catheter with a deflated balloon through the groin or arm and into a clogged artery. The balloon is then inflated, which enlarges the artery and compresses the blockage. Coronary artery disease can also be treated through bypass surgery, which is performed by taking a blood vessel from another part of the body and constructing an alternate path around the blocked part of the artery.

Prognosis

In most cases the prognosis for Tangier disease is quite good. People who develop heart disease may,

however, have a decreased lifespan depending on the severity of the disease and the quality of medical treatment.

TAR syndrome

Definition

Thrombocytopenia-absent radius (TAR) syndrome is a rare condition that is apparent at birth. Affected infants are born with incomplete or missing forearms. Typically, the bone on the thumb side of the forearm (radius) is absent, but other bones may be missing or abnormally formed. TAR syndrome also causes life-threatening bleeding episodes due to low levels of platelets in the blood (thrombocytopenia). It is inherited in an autosomal recessive manner.

Description

Dr. S. Shaw first wrote about two siblings (a brother and a sister) with missing forearms and bleeding problems in 1956. Thirteen years later, Dr. Judith Hall gave the name and acronym of TAR syndrome to the disorder. She described three families containing nine individuals. TAR syndrome has also been called the tetraphocomelia-thrombocytopenia syndrome.

KEY TERMS

Cordocentesis—A prenatal diagnostic test, usually done between 16 and 30 weeks of gestation. Using ultrasound guidance, a thin needle is introduced through the abdomen into the amniotic sac. A blood sample is taken directly from the umbilical cord. Tests can then be done on the blood sample.

Intracranial hemorrhage—Abnormal bleeding within the space of the skull and brain.

Tetralogy of Fallot—A congenital heart defect consisting of four (tetralogy) associated abnormalities: ventricular septal defect (VSD—hole in the wall separating the right and left ventricles); pulmonic stenosis (obstructed blood flow to the lungs); the aorta "overrides" the ventricular septal defect; and thickening (hypertrophy) of the right ventricle.

Tetraphocomelia—Absence of all, or a portion of, all four limbs. The hands or feet may be attached directly to the trunk.

Thalidomide—A mild sedative that is teratogenic, causing limb, neurologic, and other birth defects in infants exposed during pregnancy. Women used thalidomide (early in pregnancy) in Europe and in other countries between 1957 and 1961. It is still available in many places, including the United States, for specific medical uses (leprosy, AIDS, cancer).

The forearm is comprised of two bones. The radius is the long bone on the thumb side of the forearm. The ulna is the long bone on the little finger side. In TAR syndrome, the radius is missing on each forearm. Many times the ulna may also be missing or shorter than normal.

As these bone deficiencies are quite obvious at birth, the forearms will look very short. In fact, the hand looks as if it comes directly from the elbow. In more severe cases, the bone of the upper arm is also missing, with the hand connected to the shoulder. Approximately 50% of the time, there are other skeletal abnormalities, particularly in the lower limbs.

Each individual seems to be affected somewhat differently. For instance, some individuals with TAR syndrome might have one arm longer than the other arm; another might have both arms short, and bones missing in the feet; a third person might have all four limbs severely affected. The one constant feature is the absence of the radius bone. The forearm defects cause the hands to

Brian Hinman, a high school student with TAR syndrome, prepares to jump in the water during a swim meet. (*P Images/Laramie Boomerang/Andy Carpenear*)

be bent inward toward the body. However, the four fingers and thumb usually look normal.

The other main feature of the syndrome is thrombocytopenia. Thrombocytopenia means abnormally low levels of platelets in the blood. Platelets are made from cells called megakaryocytes. The megakaryocytes are formed in the red bone marrow, lungs, and spleen. In TAR syndrome, the megakaryocytes are either absent, decreased in number, or not formed properly. Therefore, the platelets are not properly made. The exact reason remains unknown.

When injury occurs, platelets are needed so that the blood can clot. The process is called blood coagulation. The platelets help initiate this process by attaching to the injured tissue, and clumping together, almost like a temporary patch. The platelets then release an enzyme called thromboplastin. Thromboplastin acts to cleave a

particle called fibrinogen (also in the blood) to fibrin. Fibrin is a hard substance that attaches to the injured area, and forms a meshwork (a blood clot). Along with other clotting factors, this permanently stops the bleeding.

In TAR syndrome, the normal process of making platelets is defective. The effect of this is excessive bleeding and bruising. These individuals have frequent nosebleeds and their skin bruises more easily. The platelet problem makes them more prone to bleeding inside the body, such as in the kidney or lungs. Bleeding can also occur inside the brain (intracranial hemorrhage), and be so severe that these infants die from the internal bleeding.

Genetic profile

There have been numerous instances of siblings, each with TAR syndrome. The parents were not affected.

A few families have also been seen where the parents were said to be closely related (i.e., may have shared the same altered gene within the family). For these reasons, TAR syndrome is most likely an autosomal recessive disorder. Autosomal means that both males and females can have the condition. Recessive means that both parents would be carriers of a single copy of the responsible gene. Autosomal recessive disorders occur when a person inherits a particular pair of genes that do not work correctly. The chance that this would happen to children of carrier parents is 25% (1 in 4) for each pregnancy.

It is known that the limbs (arms, legs), the heart, and the precursors of the blood system form between the fourth and eighth week of pregnancy. The birth defects seen in TAR syndrome must occur during this crucial period of development. TAR syndrome is caused by mutations in the *RBM8A* gene.

Demographics

TAR syndrome affects both males and females equally. It most likely occurs in every racial and ethnic group. It is estimated that 1 in every 250,000 infants are born with TAR syndrome. In all, more than 200 individuals with this disorder have been described in the medical literature.

Signs and symptoms

Aside from the limb deficiencies and the thrombocytopenia, the heart can also be affected. Around one-third of these infants are born with heart defects. These are usually found at birth. The heart problems include holes in the atrial chamber of the heart (atrial septal defect) and tetralogy of Fallot. The name tetralogy of Fallot means there are four different defects of the heart. Because of the high risk for excessive bleeding, these infants are not good candidates for heart surgery. Some of them have died from heart failure.

Diagnosis

Diagnosis of TAR syndrome is made with the use of x-rays of the bones, and by testing for low platelet levels in the blood at birth. TAR syndrome can be diagnosed during pregnancy. By using ultrasound (sound waves) at around 16 to 20 weeks of pregnancy, the shortening of the arms can be seen. A second test is then done called cordocentesis. In this procedure, using ultrasound guidance, a thin needle is introduced through the mother's abdomen into the amniotic sac. A blood sample is taken directly from the umbilical cord. With this blood sample, a count of the platelets can be done. If the platelet count is low, along with the short arms (absent radii), the diagnosis of TAR syndrome is made.

QUESTIONS TO ASK YOUR DOCTOR

- How did TAR disease get its name?
- What do scientists know about the genetic basis of this disorder?
- What information can a genetic counselor provide me with about TAR disease?
- What are the problems that a child born with TAR disease will have to deal with in her or his life?

Treatment and management

Surgery is sometimes done in an attempt to straighten and improve the use of their hands. They may wear corrective braces for the forearms. Many of these individuals develop arthritis, especially of the wrists and knees as they get older. This may further limit the use of their hands and legs.

Prognosis

About 40% of these individuals die in infancy, usually due to severe bleeding episodes. Cow's milk allergy or intolerance is a common problem. Stomach infections seem particularly threatening to these infants, and can also trigger the bleeding episodes. The thrombocytopenia is treated with platelet transfusions, which may or may not control the bleeding, and death may occur.

The thrombocytopenia seen in TAR syndrome does improve with age. If these individuals survive the first two years of life, they appear to have a normal lifespan. However, the easy bruising continues throughout life. Many females with TAR syndrome also have abnormal menstrual periods, possibly related to the thrombocytopenia.

However, most individuals with TAR syndrome learn to adapt well to their disability, and lead productive lives.

Tay-Sachs disease

Definition

Tay-Sachs disease is a genetic disorder caused by a missing enzyme that results in the accumulation of a fatty substance in the nervous system. This results in disability and death.

Description

Gangliosides are a fatty substance necessary for the proper development of the brain and nerve cells (nervous system). Under normal conditions, gangliosides are continuously broken down, so that an appropriate balance is maintained. In Tay-Sachs disease, the enzyme necessary for removing excess gangliosides is missing. This allows gangliosides to accumulate throughout the brain, and is responsible for the disability associated with the disease.

Risk factors

People at highest risk for Tay-Sachs are those who have a family history of the condition and who are of Jewish or French-Canadian ancestry (from the St. Lawrence River Valley of Quebec) or members of the Cajun population in Louisiana.

Genetic profile

Tay-Sachs is caused by a defective *HEXA* gene, located on chromosome 15. The *HEXA* gene provides

instructions for making an enzyme called beta-hexosaminidase A. Without this enzyme, gangliosides cannot be degraded. They build up within the brain, interfering with nerve functioning. Because it is a recessive disorder, only people who receive two defective genes (one from the mother and one from the father) will actually have the disease. People who have only one defective gene and one normal gene are called carriers. They carry the defective gene and thus the possibility of passing the gene and/or the disease onto their offspring.

When a carrier and a noncarrier have children, none of their children will actually have Tay-Sachs. It is likely that 50% of their children will be carriers themselves. When two carriers have children, their children have a 25% chance of having normal genes, a 50% chance of being carriers of the defective gene, and a 25% chance of having two defective genes. The two defective genes cause the disease itself.

Demographics

Tay-Sachs disease is very rare in the general American population but particularly common among Jewish people of eastern European and Russian (Ashkenazi) origin. About 1 out of every 3,600 babies born to Ashkenazi Jewish couples will have the disease. Tay-Sachs is also more common among certain French-Canadian and Cajun French families.

Signs and symptoms

Classic Tay-Sachs disease strikes infants around the age of six months. Up until this age, the baby will appear to be developing normally. When Tay-Sachs begins to

A retinal photograph showing Tay-Sachs disease. People with this disorder have a cherry-red spot at the back of the eye. (Ralph C. Eagle, Jr./Science Source)

show itself, the baby will stop interacting with other people, and develop a staring gaze. Normal levels of noise will startle the baby to an abnormal degree. By about one year of age, the baby will have very weak, floppy muscles, and may be completely blind. The head will be quite large. Patients also present with loss of peripheral (side) vision, inability to breathe and swallow, and paralysis as the disorder progresses. Seizures become a problem between ages one and two, and the baby usually dies by about age four.

A few variations from this classical progression of Tay-Sachs disease are possible:

- Juvenile hexosaminidase A deficiency. Symptoms appear between ages 2 and 5; the disease progresses more slowly, with death by about 15 years of age.
- Chronic hexosaminidase A deficiency. Symptoms may begin around age 5, or may not occur until age 20–30. The disease is milder. Speech becomes slurred. The individual may have difficulty walking due to weakness, muscle cramps, and decreased coordination of movements. Some individuals develop mental illness. Many have changes in intellect, hearing, or vision.

Diagnosis

Examination

Examination of the eyes of a child with Tay-Sachs disease will reveal a very characteristic cherry-red spot at the back of the eye (in an area called the retina).

Tests

Prenatal tests such as amniocentesis and chorionic villus sampling (CVS) can diagnose the disease before birth. Amniocentesis is usually done between 16 and 18 weeks of pregnancy. In this test, the doctor draws a sample of the fluid that surrounds the fetus. The fluid contains fetal cells, which are tested to see if they contain hexosaminidase A. A carrier will have about half of the normal level of hexosaminidase A present, while a patient with the disease will have none.

Treatment and management

Providing good, supportive care and treating the symptoms as they arise is the only way to treat Tay-Sachs; there is no way to treat the disease itself. Researchers are investigating whether stem cell transplants could help babies with Tay-Sachs. However, as of 2015, stem cell transplantation had not yet been successful in stopping or reversing brain damage, and the treatment also carries a high risk of death. Prevention involves identifying carriers of the disease and providing them with appropriate information concerning the chance of their

QUESTIONS TO ASK YOUR DOCTOR

- Is stem cell transplant a possible option?
- Should I get tested for Tay-Sachs before I become pregnant if I'm of eastern European and Russian origin?

offspring having Tay-Sachs disease. When the levels of hexosaminidase A are half the normal level, a person is a carrier of the defective gene. Blood tests of carriers reveals reduction of hexosaminidase A.

Prognosis

Children born with infantile Tay-Sachs, even with the best available care, usually die before the age of five. Children born with juvenile Tay-Sachs usually die before the age of 15.

Laith Farid Gulli, MD
and Tish Davidson, AM

Teratogen

Definition

A teratogen is any environmental influence that adversely affects the normal development of the fetus.

Description

Abnormal fetal development may result from exposure to a teratogen. There are four different teratogen categories: physical agents (radiation and hyperthermia), metabolic conditions affecting the mother, infection, and drugs (like thalidomide) and alcohol.

Physical agents

Hyperthermia

Women whose body temperature is raised while pregnant may have abnormalities result in their fetus. The rise in body temperature can be caused by infection or by spending time in hot areas such as a sauna or hot tub.

Ionizing radiation—mutagens versus teratogens

Any outside agent (like radiation) interfering with the process of development is considered a teratogen. Development is the process in which a tiny mass of undifferentiated cells (the embryo) multiplies and differentiates into the kidney, liver, heart, bones, muscles, and so on. Mutagens, however, are agents that directly affect and disrupt DNA, the genetic blueprint of an organism. Some agents, like radiation, are mutagens and teratogens. Ionizing radiation can cause defects either in development, or it can damage DNA directly.

Metabolic disease

Infants of women with metabolic disorders have increased risks for abnormalities. Diabetic women, for example, are three to four times more likely to have fetuses with congenital abnormalities than infants of mothers without diabetes. The metabolic disease of the mother can have genetic or other causes.

Infection

There are a number of known infectious organisms that are teratogenic to the fetus, some of which cause damage directly and some of which damage the fetus by causing a fever and raising the temperature of the mother.

Alcohol and drugs

Thalidomide

A dramatic example of a teratogen is thalidomide. In the early 1960s, it was shown that more than 7,000 women who took the antinausea drug thalidomide during their pregnancy had children with very short or absent arms and legs. Other abnormalities were also seen in the children, such as the absence of ears, as well as heart and intestinal malformations. Affected infants were born to women who took thalidomide during the critical time period, also known as the period of susceptibility.

Period of susceptibility: The example of thalidomide

Thalidomide also teaches the importance of timing in the action of teratogens. Only a small amount of thalidomide was necessary to cause birth defects, but it had to be taken between 34 and 50 days after conception in order to harm the embryo. The time when teratogens can act, in this case from day 34 to day 50 after conception, is called the period of susceptibility. Since organ development in the unborn child occurs at different times, it was shown that taking thalidomide on different days caused the infants to have a variety of defects (heart vs. ears vs. limb formation). Drugs very often affect specific parts of the process of development. Before, or after, the processes take place, the drug will have no effect. Of course many teratogens, like thalidomide, work on a number of different developmental processes at different times (sometimes they are consecutive times, or they may be nonconsecutive; for example, from days 16 to 20 and days 24 to 48). The period of susceptibility of the fetus to most teratogens is between the third and eighth week after conception.

Dose and duration: The example of alcohol

The most common teratogen, alcohol, illustrates the important concept that the dose of a teratogen (for example, the number of alcoholic drinks a mother has) and duration of exposure to a teratogen (for example, the number of days a mother drinks alcohol) both play an important role in the effect of a teratogen. Alcohol can have a wide range of effects on a fetus, from no mental change or very mild mental changes (usually a small dose of alcohol) to full-blown fetal alcohol syndrome, in which the infant is severely retarded. Even two glasses of alcohol

can be teratogenic to a fetus, but the mental retardation and characteristic facial changes seen in full-blown fetal alcohol syndrome generally requires the mother to drink 2–3 oz. of alcohol per day for a sustained period of time (the exact amount of time is not known) during pregnancy. Thus, dose and duration help determine the severity of a teratogen's effects.

Other factors that affect teratogens

Although the dose and duration are important in determining how much of an effect alcohol will have on the fetus, other factors have an impact too. When normal mice and mutant mice are given the same dose of a particular teratogen, the mutant mice are affected much more severely. This means that in humans, the genetic makeup of the fetus helps determine to what extent the teratogen will affect the fetus. A fetus with one particular set of genes might be severely affected by the mother drinking one glass of alcohol, while another fetus may be unaffected by the first or even second glass of alcohol. The outcome of teratogens probably depends on a combination of factors: the mother's condition (genetic or otherwise), the genetic background of the fetus, and the dose and duration of the teratogen. However, the importance of each factor probably varies greatly from teratogen to teratogen and from individual to individual.

Although the discussion of these teratogenic concepts has revolved around examples from the category of drugs and alcohol, the concepts may be applied to any of the categories of teratogens.

Demographics

Exact numbers of infants affected by teratogens are difficult to estimate. *Langman's Medical Embryology* states 4%–6% of all infants will have major developmental or genetic abnormalities. This source estimates that of the children with major abnormalities, 10% can be attributed to teratogens, 20%–25% can be attributed to genetic and environmental influences, and 40%–60% of the abnormalities are due to unknown causes (possibly teratogenic). That means as many as 95% of all major birth disorders may involve teratogens.

Diagnosis

The diagnosis varies from teratogen to teratogen. Some genetic diseases and teratogens can present with the same abnormalities and symptoms. If the gene causing the disorder has been isolated and is well understood, the difference between a genetic and a teratogenic disorder may be established. Many abnormalities in children go unexplained. In these cases, teratogen exposure should be considered.

Treatment, prevention, and the period of susceptibility

Treatment options and how well they work vary widely according to the teratogen. The best course is to prevent teratogen exposure, or reduce the exposure as much as possible. Prevention is complicated because very often women may not realize they are pregnant until the middle of the period of susceptibility. Substances that are not harmful to an adult, like the derivatives of retinoic acid found in a number of skin creams, alcohol, and many prescription drugs, can be extremely harmful to the fetus. Retinoic acid, for example, has a period of susceptibility from days 20–35 after conception—a time when many women might not realize they are pregnant.

Thus, women who are engaging in activities that can lead to pregnancy and want to avoid any potential damage to their fetus should attempt to avoid teratogenic substances (including a large number of over-the-counter, prescription, and illegal drugs). Alternatively, women can also prevent most damage to the fetus by closely monitoring their pregnancy status and avoiding teratogens as soon as pregnancy occurs.

Partial list of teratogens

Drugs and chemicals:

- alcohol
- aminoglycosides
- aminopterin
- antithyroid agents
- bromine
- cortisone
- diethylstilbestrol (DES)
- diphenylhydantoin
- heroin
- lead
- methylmercury
- penicillamine
- retinoic acid (Isoretinoin, Accutane)
- tetracycline
- thalidomide
- trimethadione
- valproic acid
- warfarin

Physical agents:

- hyperthermia (fever, sauna)
- ionizing radiation (x-rays)

KEY TERMS

Development—The process whereby undifferentiated embryonic cells replicate and differentiate into limbs, organ systems, and other body components of the fetus.

Maternal—Relating to the mother.

Mutagen—An environmental influence that causes changes in DNA.

Period of susceptibility—The time when teratogens can cause harm to the developing fetus.

Infectious organisms:

- Coxsackie virus
- Cytomegalovirus
- Herpes simplex virus
- Parvovirus
- Rubella
- Toxoplasma gondii
- Treponema pallidum (syphilis)

Metabolic conditions in the mother:

Thalidomide embryopathy

Definition

The term "thalidomide embryopathy" (TE) is used to describe a specific pattern of birth defects caused by a mother's use of the drug thalidomide during her pregnancy. The drug is able to cross the placenta and reaches the developing embryo, causing parts of the embryo's body to form abnormally. The most common birth defects observed in infants with TE are structural abnormalities of the arms, legs, ears, and eyes, although other organs may also be affected. The most harmful time to use thalidomide is during the first three to six weeks of pregnancy.

Description

Thalidomide was originally marketed in Germany in October 1957 as a safe, inexpensive, and effective sedative. Its use was later expanded to include treatment of insomnia, anxiety, upset stomach, and morning sickness during pregnancy. Prior to its release onto the market, thalidomide had been tested in rodents and had been deemed safe; human studies were not performed. It was made available in at least 46 countries. However, the drug was never approved for marketing in the United States due to concerns about the medication's potential side effects, one of which, peripheral neuropathy, was first recognized in 1960. Symptoms of peripheral neuropathy, or nerve damage, include burning, numbness, or tingling in the arms, legs, hands, or feet. The damage may not be reversible even after stopping the medication. Early in the 1960s, an increased number of infants with severe abnormalities of the arms and legs were observed in Germany, Great Britain, and Australia. Once it became clear that the mothers of these infants had taken thalidomide while pregnant, a connection was made between the drug and the birth defects. In 1961, the drug was withdrawn from the worldwide market. It has since become known as a powerful human teratogen, a drug or other agent proven to cause birth defects. The experience with thalidomide also led to greater overall attention to the potential effects of drug and other environmental exposures on a developing fetus,

Freddie Astbury, affected by thalidomide after his mother was prescribed it to help with morning sickness, was born with stunted arms and legs. (Paul Cooper/Rex Features/AP Images)

and to improved legislation regarding testing requirements before a new drug is released to the public.

Although the use of thalidomide decreased dramatically after 1961, it remained available in the United States and other countries on a “compassionate use” basis: physicians could obtain special permission to treat ill patients they believed could significantly benefit from the drug. Over time, it became clear that thalidomide is effective in the treatment of a number of medical conditions. This surprising resurgence of thalidomide has, in turn, led to concern over the possibility of another generation of children born with thalidomide-related birth defects. The manufacturer of thalidomide, Celgene Corporation, is working in close partnership with the U.S. Food and Drug Administration (FDA) to tightly control the use of the drug and to maintain close follow-up on all individuals to whom it is prescribed. The drug is marketed under the brand name Thalomid.

Limb abnormalities are the most readily identified, and most well-known, type of birth defect caused by prenatal thalidomide exposure. However, other types of physical problems may also occur in an exposed infant. In addition to limb abnormalities, TE may include abnormalities of the ears, eyes, kidneys, heart, intestinal tract, and nervous system. Mental retardation has been reported in approximately 5% of older individuals with TE.

Genetic profile

TE is not an inherited medical condition. However, thalidomide is a known teratogen. Therefore, women who use this medication while pregnant are at risk of having infants with physical, and possibly mental, birth defects. A woman who does not use thalidomide during pregnancy cannot have a child with TE. It is still not

entirely clear how thalidomide causes birth defects. One hypothesis is that the drug prevents formation of new blood vessels. Research is continuing in this area.

Demographics

It is estimated that 10,000–12,000 infants were born with birth defects consistent with TE following its initial period of use in the late 1950s to early 1960s. According to the Teratology Society 1998 Public Affairs Symposium, approximately 40%, or roughly 5,000, of the affected individuals survived.

In July 1998, the FDA approved the use of thalidomide in the United States, under a very tightly controlled protocol, for the treatment of erythema nodosum leprosum (ENL), a painful skin complication of leprosy. The drug has been available in South America, an area where leprosy is more common than in the United States. Reports of thalidomide-affected South American infants were published as recently as 2015.

Medical researchers are studying whether or not thalidomide may be effective in the treatment of other medical conditions, including certain skin and immunologic disorders, certain complications associated with human immunodeficiency virus (HIV) infection, and certain cancers. Although pregnancies among female patients with any of these conditions may be rare, unintended pregnancies will occur and will be at risk for fetal abnormalities if the mothers are taking thalidomide.

Signs and symptoms

TE includes a spectrum of physical abnormalities, all of which may occur at various levels of severity. An affected individual may not have every type of birth defect. All affected infants, however, have been exposed to thalidomide in early pregnancy, a time when the organs and body of an embryo are rapidly developing. Although use of thalidomide at any point in pregnancy is strongly discouraged, women who use the drug during the first six weeks of pregnancy are at the greatest risk of having children with birth defects. Rigorous control of the drug is necessary since many pregnancies are unplanned and may go unrecognized until after the drug exposure has occurred.

The clinical features of TE include the following.

Limb defects

The most well-known type of abnormality is referred to as phocomelia. Phocomelia occurs when most of the bones in the arms or legs are missing, and the hand or foot is attached directly to the body, similar to a flipper. Radial aplasia, or absence of the thumb and connecting bone in the forearm (radius), is another common abnormality.

Abnormalities of the digits include a triphalangeal thumb (three small bones in the thumb, rather than two, such that the thumb looks like a finger), or an absent (hypoplastic) thumb only. Similar defects of the legs may also occur. Frequently, affected infants have abnormalities on both sides of their bodies, involving all four extremities.

Ears

Malformations of the ears are common. These range from complete absence of the ear (severe microtia, also sometimes referred to in the medical literature as anotia) to mild changes in the appearance of the external ear. Abnormalities of the inner ear frequently cause deafness. Inner ear malformations may occur even if the external ear appears normal.

Eyes

A range of eye abnormalities have been reported, including a very small eye (microphthalmos), glaucoma, strabismus, cataract, and abnormal production of tears.

Other

- Structural heart defects.
- Kidney malformations, most often an absent or misplaced kidney.
- Abnormalities of the intestinal system.
- Structural defects of the spine and chest.
- Central nervous system abnormalities, such as mental handicap, described in a small percentage of older individuals with TE.
- Paralysis of the nerves of the face on either one side, both sides equally, or both sides but asymmetrically.
- An increased risk for early infant death, particularly among those infants with severe abnormalities of their internal organs.

Diagnosis

Exposure to thalidomide during the first six weeks of pregnancy poses a significantly increased risk of having a child with TE. It is important to note that the exact dosage of the drug during this period is irrelevant. Thalidomide is rapidly broken down in the mother's body and is therefore able to reach her developing embryo quickly. There is no direct genetic test to accurately diagnose all thalidomide-related birth defects before delivery. However, prenatal ultrasound examinations may be used to identify major structural abnormalities, such as those involving the limbs, heart, kidneys, and intestinal tract. A careful physical examination by a knowledgeable and experienced physician(s) is warranted after birth to document the nature and severity of any thalidomide-induced

KEY TERMS

Cataract—A clouding of the eye lens or its surrounding membrane that obstructs the passage of light, resulting in blurry vision. Surgery may be performed to remove the cataract.

Embryo—The earliest stage of development of a human infant, usually used to refer to the first eight weeks of pregnancy. The term *fetus* is used from roughly the third month of pregnancy until delivery.

Erythema nodosum leprosum—A complication of leprosy characterized by development of small, painful swellings due to inflammation of a blood or lymph vessel. It is often accompanied by inflammation of a nerve or nerves, causing decreased function of the affected area.

Glaucoma—An increase in the fluid eye pressure, eventually leading to damage of the optic nerve and ongoing visual loss.

Immunologic—Related to immunology, the study of how the body's immune system fights disease. Many immunologic disorders are characterized by the body's use of antibodies.

Insomnia—An inability to either fall or stay asleep, particularly at a time of day when sleep is expected. A number of medications are available, and may be used, for treatment.

Leprosy—A chronic, contagious skin and nervous system disease that leads, in the more serious form, to numbness, muscle weakness, and paralysis. Leprosy is sometimes referred to as Hansen's disease.

Placenta—The organ responsible for oxygen and nutrition exchange between a pregnant mother and her developing baby.

Sedative—Medication that has a soothing or tranquilizing effect.

Strabismus—An improper muscle balance of the ocular muscles resulting in crossed or divergent eyes.

birth defects. Additional studies, such as hearing evaluations, are also indicated.

Treatment and management

Management of the individual with TE is primarily symptomatic. Specialized medical care, such as heart surgery, may be necessary in certain situations, and should be determined on a case-by-case basis. Deaf individuals may require hearing aids and/or will need to learn sign

QUESTIONS TO ASK YOUR DOCTOR

- Is my child a candidate for a hearing aid or devices to assist with mobility?
- Could my child be helped by physical or occupational therapy?
- If I do not take thalidomide again, is there a continued risk of having another child with TE?
- How long does it take for thalidomide to be completely out of my system?

language. Severe limb abnormalities may lead to the use of a wheelchair or other device to assist in mobility.

In order to try to minimize the number of future children born with TE, the drug manufacturer and the FDA implemented the System for Thalidomide Education and Prescribing Safety (S.T.E.P.S.) program in 1998. The goals of the program are threefold: (1) to limit the risk of fetal exposure to thalidomide; (2) to enforce universal compliance of patients, physicians, and pharmacists with the designated components of the program; and (3) to support appropriate, controlled use of the drug. To achieve this, the S.T.E.P.S. program requires informed consent from all patients to whom the drug will be given. Face-to-face counseling, a patient information booklet, and a videotape are all used to review the potential benefits and side effects of the medication. Plans for birth control (contraception) and/or abstinence from sexual intercourse are also discussed. All women of childbearing age must agree to a pregnancy test prior to receiving their medication and at frequent intervals during treatment. Two methods of birth control are additionally required. Physicians who will be prescribing thalidomide must be registered in the S.T.E.P.S. program and must agree to follow each step of the program. Prescriptions may only be filled at registered pharmacies. No more than a one-month supply of the medication may be provided at one time; there are no automatic refills. It is recommended that women receive only a one-week supply, particularly during the first four weeks of treatment. Weekly refills are granted only with proof from a physician of a negative pregnancy test. In the event that a woman becomes pregnant, or suspects that she may be pregnant, an immediate referral is made for medical evaluation. Follow-up care is provided, and a database of all patients taking thalidomide is maintained.

Despite this unprecedented level of strict control, the S.T.E.P.S. program is unlikely to completely prevent the birth of *every* child in the United States with TE. Other countries in which the drug has been approved for use

have been encouraged to develop similar methods to follow outcomes of pregnancies exposed to thalidomide. In the meantime, research is continuing to find drugs that will be as effective as thalidomide without the same dangers to embryonic development.

Prognosis

There is no data addressing long-term survival rates among individuals with TE. Nonetheless, the presence and severity of thalidomide-related birth defects, particularly those involving the heart, would be expected to have the greatest impact on longevity. Severe heart malformations that cannot be corrected by surgery are likely to lead to early death. In the absence of such abnormalities, a normal lifespan is anticipated.

Thanatophoric dysplasia

Definition

Thanatophoric dysplasia is one of the most common and most severe forms of dwarfism. Affected infants have marked shortening of their arms and legs, a small chest,

X-ray of a newborn baby with thanatophoric dysplasia. (Scott Camazine/Science Source)

and a relatively large head. Most die within a few days after birth; longer-term survivors have been reported but are rare.

Description

Thanatophoric dysplasia (TD) was first described in 1967 to refer to infants with a severe form of dwarfism who died within the first hours of life. The word “thanatophoric” is derived from the Greek word “thanatophorus,” which means “death-bringing.” The term “thanatophoric dwarfism” is occasionally used, but the word “dysplasia,” which refers to any disorder in growth, has become the preferred terminology.

Two distinct types of TD were delineated in 1987. Affected infants are divided based on their particular combination of physical features and skeletal findings. While all individuals with TD have micromelia, or abnormally small or short arms and legs, differences in the length and shape of the long bones of the thigh (femur) can be used to distinguish between TD types 1 (TD1) and 2 (TD2). Infants with TD1 have curved, “telephone-receiver”-like femurs. In contrast, the femurs of infants with TD2 are longer and straighter.

The presence of skull abnormalities is another important distinction between the two types: infants with TD2 typically have a severe abnormality of the bones of the skull, referred to as cloverleaf skull or *kleeblattschadel* anomaly. The skull of a normal infant is composed of several segments of bone, some of which are completely joined together or fused by the time of delivery. Their lines of fusion are referred to as sutures. Some sutures are only partially fused, leaving soft, skin-covered openings that will gradually close over the first year of life. Premature closure of these sutures leads to a condition called craniosynostosis. Craniosynostosis can cause an abnormal skull shape and if not eventually corrected by surgery, prevents normal growth of the brain. The most extreme form of craniosynostosis, as seen in infants with TD2, causes a severely abnormal skull whose shape resembles that of a cloverleaf. Although milder forms of craniosynostosis may be found in infants with TD1, cloverleaf skull is not typically present.

Other bone abnormalities occur in both TD types 1 and 2, including an abnormal shape of and spacing between the bones in the spine (vertebrae), shortened ribs, and small pelvic bones. Most of the other organs of the body, with the exception of the brain, are normal, although occasional abnormalities of the kidneys have been reported. A variety of abnormal changes in the structure of the brain have been described. The few cases of children with TD who have survived past infancy have been severely mentally and physically handicapped.

The most common cause of death among individuals with TD is respiratory insufficiency. The small chest and limited growth of the lungs are the primary reasons for the breathing problems seen in TD. However, associated abnormalities of the central nervous system are most likely also involved since these interfere with the body’s ability to regulate normal breathing.

Genetic profile

Both types of thanatophoric dysplasia occur as sporadic, autosomal dominant conditions. Only one copy of the altered gene causing TD needs to be present in order for the condition to occur. Males and females are equally likely to be affected. The parents of an affected child do not have TD and are normal. Thus, in most cases, it is likely that a new genetic mutation that causes TD occurred in either the egg or sperm cell that gave rise to that particular pregnancy. Such a mutation cannot be made to happen; it occurs simply by chance. There is a very low risk of recurrence, or chance of another affected child in a future pregnancy. Unfortunately, families have been described with more than one child with TD. The most likely explanation in these families is gonadal mosaicism.

Gonadal mosaicism occurs when an adult has a mixed population of normal and abnormal cells in his or her gonads (testes or ovaries), but all of the other cells in that individual's body are presumably normal. Most sperm or egg cells from these gonads would be normal and would not have a TD mutation; however, an unknown percentage would carry the mutation. As a result, even though the parents would be normal, he or she could, with the same or a different partner, have another child with TD. It is virtually impossible to prove whether or not a parent has gonadal mosaicism. Even so, all parents of an affected child are counseled that gonadal mosaicism in one of them is a possibility.

Thanatophoric dysplasia is caused by mutations in the fibroblast growth factor receptor 3 gene (*FGFR3*), located on the short arm of chromosome 4 at band 16.3 (abbreviated as 4p16.3). The fibroblast growth factors are a family of important proteins in the human body that are involved in the production of new cells and new blood vessels as well as in the healing of wounds. Mutations in each of the fibroblast growth factor genes (*FGFR1*, 2, and 3) have been linked to a variety of genetic conditions. The *FGFR3* protein is primarily found in cartilage and the central nervous system. Different mutations in the *FGFR3* gene have been associated with other skeletal dysplasias, most notably achondroplasia and hypochondroplasia.

As might be expected, different mutations in *FGFR3* have been found in patients with TD1 versus those with TD2. A wider variety of mutations have been identified among infants with TD1. One predominant mutation has been present in nearly all cases of TD2 studied so far. Regardless of the specific mutation, the net effect of each of the mutations in both TD1 and TD2 is the same: the linear growth of bone is prevented, resulting in very short, small bones.

Demographics

Thanatophoric dysplasia is the most common lethal skeletal dysplasia, with an estimated incidence of 1 in 35,000–50,000 births. It has been described in all races and ethnic groups.

Signs and symptoms

Infants with TD are typically identified either during pregnancy or at the time of birth. Affected pregnancies are often complicated by polyhydramnios, or excess amniotic fluid around the fetus. As a result, the mother often appears more pregnant than she actually is. It is common for a prenatal ultrasound examination to be performed to rule out a fetal birth defect as the cause. The serious limb abnormalities typical of TD are often

KEY TERMS

Achondroplasia—An autosomal dominant form of dwarfism caused by a defect in the formation of cartilage at the ends of long bones. Affected individuals typically have short limbs, a large head with a prominent forehead and flattened profile, and a normal-sized trunk.

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10–12 weeks of gestation. Under ultrasound guidance a needle is inserted either through the mother's vagina or abdominal wall and a sample of cells is collected from around the fetus. These cells are then tested for chromosome abnormalities or other genetic diseases.

Hypochondroplasia—An autosomal dominant form of dwarfism where physical features are similar but milder than those of achondroplasia. Affected individuals have mild short stature and a normal facial appearance.

identified in this way. Polyhydramnios may also lead to an increased chance of early labor and premature delivery. The pregnant woman may require more intensive monitoring of her pregnancy.

At birth, newborns with TD typically have a very large head with a prominent forehead, a flattened bridge of the nose, and prominent, bulging eyes. Their limbs are extremely short and are often held extended out from the rest of the body. The neck is short, the chest is narrow, and the belly appears unusually large, giving an overall resemblance to a pear. The shape of the skull may be abnormal due to either cloverleaf skull or a milder form of craniosynostosis. Newborns are often rather floppy, or hypotonic, with poor muscle tone and absent primitive neurologic reflexes. Breathing is very difficult due to the small chest and lungs, often leading to the use of a ventilator to prolong survival.

The physical appearance of individuals with TD who survive the neonatal period does not dramatically change over time. Affected children remain very small and have

QUESTIONS TO ASK YOUR DOCTOR

- What type of supportive measures will be most helpful?
- How can I best determine if a future pregnancy will result in a child with TD?
- What is your level of certainty that my child has either TD1 or TD2?
- At what point should I have genetic testing?

limited potential to walk or move about unaided. Intellectual disability due to structural brain malformations has been reported. Seizures and hearing loss frequently develop.

Diagnosis

Prenatal diagnosis of TD is possible based on ultrasound examination, usually during the second half of pregnancy. However, it is important to realize that many of the physical abnormalities seen in fetuses with TD such as an enlarged head and shortened long bones, may also be found in fetuses with other forms of skeletal dysplasia. Consequently, while ultrasound may suggest a diagnosis of a skeletal dysplasia, it may not be possible to confirm a diagnosis of TD until after birth.

Upon delivery, a careful examination of the infant should be performed to look for many of the more obvious external features of TD. Radiologic studies are extremely important, particularly to distinguish between TD1 and TD2. X-ray will confirm the marked shortening of the long bones, identify curved or straight femurs, document the shape and appearance of the spinal vertebrae, and reveal the extent of craniosynostosis. An autopsy, including x-rays, is highly recommended on any stillborn infant with TD to confirm the diagnosis. Mutation studies by analysis of the *FGFR3* gene are being used more often to confirm a diagnosis of TD and to determine TD type. Perhaps the greatest benefit of direct genetic testing is for those parents who have been told by a prenatal ultrasound examination that their unborn child has a serious bone dysplasia. An amniocentesis for additional genetic studies may be offered. Further clarification of the diagnosis allows for more refined counseling regarding the infant's likely prognosis. Termination of the pregnancy may be an option for some couples. For those couples wishing to continue an affected pregnancy, plans can be made for the remaining prenatal care, especially given the risk for polyhydramnios and/or early labor and

delivery. Careful consideration may be given as to the level of intervention and medical care desired for the infant after birth.

Knowledge of the specific TD mutation is also helpful in planning care for any future pregnancy. Despite the sporadic nature of TD, a couple with a history of one affected child has a small risk of having a second affected child due to the possibility of gonadal mosaicism. Prenatal testing in a new pregnancy, such as chorionic villus sampling (CVS) or amniocentesis, may be offered to look for a TD mutation. However, in order for this to be possible the TD mutation in the previous child must have been determined.

Studies are ongoing to assess whether or not three-dimensional ultrasound, in contrast to the current, much more widely available, two-dimensional ultrasound, may be used to accurately prenatally diagnose TD and other skeletal dysplasia. If effective, additional prenatal studies could become less common; however, early results have shown no significant improvement in the detection or diagnosis of TD and related disorders. The present standard of care therefore remains a prenatal ultrasound examination, if available, physical evaluations after delivery, and identification of the underlying genetic mutation, whenever possible.

Treatment and management

The treatment and care of an infant with TD is mainly supportive. The poor prognosis associated with TD should be discussed. Infants who survive the newborn period will require intensive, ongoing medical care.

Prognosis

Nearly all infants with TD, both types 1 and 2, die either at the time of delivery or shortly thereafter due to severe respiratory distress. Aggressive medical treatment after birth cannot always help affected infants live even a short amount of time. Prolonged survival has been reported but is highly unusual. Survival is associated with poor growth and development, and with continuing, serious respiratory problems.

Thoracic aortic aneurysms

Definition

An aneurysm is an abnormal bulge or ballooning in an artery wall caused by a weakness in the wall. A thoracic aortic aneurysm is one that occurs in the upper part of the aorta in the chest above the heart. It is also called thoracic aortic aneurysm and dissection (TAAD), because a large aneurysm can burst or infiltrate the artery wall (dissection) and cause life-threatening bleeding. Familial TAAD runs in families and can be caused by mutations in various genes.

Description

The aorta is the largest artery in the body. It carries oxygen-rich blood from the heart through the chest and abdomen to the rest of the body. Most aneurysms occur in the aorta. Thoracic aortic aneurysms occur in the aorta in the chest, and abdominal aortic aneurysms occur in the portion of the aorta that runs through the abdomen. An aortic rupture is a burst aneurysm that causes bleeding within the body. An aortic dissection occurs when pumped blood splits the layers of a weakened artery wall and allows blood to leak between the layers. Most deaths

X-ray of the chest of a 68-year-old woman with an aortic aneurysm (upper center). (SPL/Science Source)

from aortic aneurysms are caused by ruptures and dissections. Small, slow-growing thoracic aortic aneurysms may never cause a problem, but large, fast-growing aneurysms can cause life-threatening rupture or dissections.

Thoracic aortic aneurysms are most often caused by atherosclerosis (hardening of the arteries), which is more common in people with high cholesterol or long-term high blood pressure (hypertension) and in smokers. More than 70% of people with thoracic aortic disease have uncontrolled hypertension. Age-related changes to the artery wall, inflammation of the aorta, syphilis, and injuries from falls or motor-vehicle accidents are also risk factors for TAAD.

Familial TAAD is caused by inherited problems with the aorta. Familial TAAD can cause the aorta to weaken and stretch (aortic dilatation), which can lead to an aneurysm or aortic dissection. Aortic aneurysms and dissections can rupture and/or reduce blood flow to the brain and other vital organs. Other arteries may also be affected. TAAD can also be caused by inherited connective-tissue disorders such as Marfan syndrome or Ehlers-Danlos syndrome.

Genetic profile

About 20% of TAADs are familial and can be caused by mutations in several different genes. Familial TAAD is inherited in an autosomal dominant pattern, which

means that an individual need only inherit one mutated gene from an affected parent to develop TAAD, even if the second gene, inherited from the other parent, is normal. However, some people who inherit a TAAD-associated gene mutation never develop aortic abnormalities—a phenomenon known as reduced penetrance and indicating that the corresponding normal gene is able to compensate for the defect.

Between 14% and 20% of people with familial TAAD have mutations in the *ACTA2* gene. This gene produces a protein called smooth muscle alpha-2 actin, which is an important component of the vascular smooth muscle cells (SMCs) that form layers in the walls of the aorta and other arteries. Smooth muscle alpha-2 actin forms the protein core of structures called sarcomeres that enable muscles to contract and the arteries to hold their shape while blood pumps through them. The *ACTA2* (ACTin, Alpha2, smooth muscle, aorta) gene mutations that cause familial TAAD change single amino acids (building blocks) in the smooth muscle alpha-2 actin protein. This results in an abnormal protein that interferes with sarcomere function and results in stretching of the arteries as the blood is pumped through. Because the blood pumped directly from the heart to the aorta has the most force, the aorta is especially vulnerable to stretching. This can result in dilatation, aneurysms, and dissections. Whereas mutations in *ACTA2* disrupt the thin filaments in the SMC contractile complex, mutations in the *MYH11* gene, which produces myosin heavy chain 1 in smooth muscle, disrupt the thick filaments in the SMC contractile complex. In both cases, the ability of SMCs to contract in response to blood pressure is reduced.

About 2.5% of people with familial TAAD have mutations in the *TGFBR2* gene that produces a protein called transforming growth factor-beta (TGR-beta) receptor type 2. This receptor binds TGR-beta on the surfaces of cells, causing the receptor to transmit signals to the inside of the cell to control cell growth and division (proliferation) and differentiation into specific types of cells. The TGR-beta receptor 2 is also involved in the formation of the extracellular matrix that fills the spaces between cells. Mutations in *TGFBR2* change the structure of the receptor, which disrupts signaling within the cell and impairs cell growth and development, resulting in aortic abnormalities.

In 2013, researchers identified a rare mutation in the *PRKG1* gene. This mutation changes a single amino acid in an enzyme called type 1 cGMP-dependent protein kinase (PKG-1) and causes familial TAAD. The PKG-1 enzyme controls SMC relaxation when it is activated by binding the nucleotide cGMP. The majority of affected individuals in four families had acute aortic dissections at relatively young ages, some as young as 17. The amino

KEY TERMS

ACTA2—The gene that encodes smooth muscle alpha-2 actin; up to 20% of familial thoracic aortic aneurysms and dissections (TAADs) are caused by mutations in the *ACTA2* gene.

Aorta—The largest artery in the body that carries blood through the trunk to branch arteries throughout the body.

Aortic dilatation—Weakening and stretching of the aorta that can occur with TAAD-associated gene mutations and lead to an aneurysm or aortic dissection.

Aortic dissection—A splitting of the layers of the aorta wall that causes blood to leak between the layers.

Autosomal dominant—A pattern of genetic inheritance in which only one abnormal gene is needed to express the trait or disorder.

Penetrance—The proportion of individuals who actually exhibit a trait for which they have gene or gene variant.

Smooth muscle cells (SMCs)—The layered cells in the wall of the aorta and other arteries.

acid change causes the protein to be always active, even in the absence of cGMP. This is known as a gain-of-function mutation. This constant PKG-1 activity decreases contraction of vascular SMCs by removing phosphate groups from myosin, an important muscle protein. Like other TAAD mutations, the *PRKG1* mutation is inherited in an autosomal dominant manner and appears to be very rare. It changes a highly conserved amino acid in the PKG-1 protein, meaning that this particular amino acid is present at the same position in the protein in a wide variety of organisms and suggesting that it is essential for protein structure and/or function.

In 2015, researchers identified mutations in the *MAT2A* gene that can cause autosomal dominant TAAD. The *MAT2A* gene produces a protein called methionine adenosyltransferase II alpha (MAT IIalpha). The two identified mutations were single changes in a building block (nucleotide) of the DNA sequence of the *MAT2A* gene that changed single amino acids in the protein. There are very few variations in the human *MAT2A* gene, and the two identified changes occur in amino acids that are evolutionarily conserved in the MAT IIalpha enzyme. These two mutations are believed to disrupt the enzymatic activity of the MAT IIalpha protein.

Other genes in which mutations can cause TAAD include:

- MYLK (myosin, light-chain kinase)
- TGFBR1 (transforming growth factor, beta receptor 1)
- TGFBR2 (transforming growth factor, beta 2)
- SMAD3
- FBN1

Genetic testing may be available for identified TAAD gene mutations. It is thought that mutations in other as-yet-unidentified genes may also cause rare cases of familial TAAD.

Demographics

Although aortic aneurysms are common worldwide, they usually have no symptoms unless they rupture, so their prevalence is difficult to determine. Ruptured aortic aneurysms and dissections cause nearly 30,000 deaths in the United States every year. About two-thirds of aortic dissections occur in males.

At least 20% of all TAAD are believed to be familial. The other 80% are not inherited but rather are caused by damage to the aorta wall from aging, smoking, injury, or disease. Although TAAD usually appears to be inherited in an autosomal dominant pattern, its occurrence is variable, even within affected families, and penetrance is lower in females. Mutations in the *ACTA2* gene account for 14%–20% of familial TAAD. Mutations in the *TGFBR2* gene account for about 2.5% of cases. Mutations in each of the other identified TAAD-associated genes appear to account for smaller percentages of familial TAAD.

Signs and symptoms

The development of familial TAAD varies, even within the same family. Aortic abnormalities may develop in childhood, adulthood, late in life, or not at all. Aortic dilatation usually appears first, although sometimes dissection occurs with little or no dilatation.

Aortic aneurysms can develop slowly over many years and usually have no symptoms until the aneurysm leaks or expands. Symptoms start suddenly when an aneurysm grows rapidly or ruptures or aortic dissection occurs. However, depending on the size, rate of growth, and location of the aneurysm and whether it presses against other structures, symptoms may include:

- pain in the chest, back, neck, or jaw
- swelling in the head, neck, or arms
- difficult or painful swallowing
- hoarseness
- shortness of breath

- wheezing or high-pitched breathing
- chronic cough
- coughing up of blood
- clammy skin
- nausea and vomiting
- rapid heart rate
- feeling of impending doom

An aortic dissection generally causes sudden, severe chest or back pain. It can also cause:

- pale skin color
- very faint pulse
- numbness or tingling in one or more limbs
- paralysis

Although familial TAAD is not generally associated with other signs and symptoms, some people in affected families have mild features of Marfan syndrome or Loeys-Dietz syndrome, including:

- tall stature
- stretch marks on the skin
- joint hypermobility (unusually large range of motion)
- a sunken or protruding chest

Some people with familial TAAD have:

- brain or abdominal aortic aneurysms
- congenital (present at birth) heart abnormalities
- a soft out-pouching in the lower abdomen called an inguinal hernia
- purple skin discoloration called livedo reticularis caused by abnormalities in the tiny blood vessels of the skin
- increased risk of blockages in smaller arteries that can lead to a heart attack or stroke

Diagnosis

Thoracic aortic aneurysms can be diagnosed with imaging tests, but they are usually discovered during testing performed for other reasons. These include a chest x-ray, echocardiogram, or a computed tomography (CT) scan or magnetic resonance imaging (MRI) of the chest. A CT scan will reveal the size of the aorta and the exact location of the aneurysm. An aortogram—x-rays taken after the aorta is injected with a dye—can identify aneurysms, as well as any branches of the aorta that may be involved.

Because aneurysms do not usually cause symptoms unless they rupture or a dissection occurs, and physical examinations are usually normal, ultrasound screening is recommended for people between the ages of 65 and 75 who have a family history of TAAD, as well as for men who have ever smoked.

QUESTIONS TO ASK YOUR DOCTOR

- Should I be screened for thoracic aortic aneurysms, since they run in my family?
- Is genetic testing available for thoracic aortic aneurysms?
- What are the symptoms of thoracic aortic aneurysms?
- What are the chances that I will pass thoracic aortic aneurysm and dissection on to my children?

Treatment and management

Treatment of thoracic aortic aneurysm depends on its size and how fast it is growing. No treatment other than “watchful waiting” may be prescribed if the aneurysm is small and slow growing. Medications can also be prescribed. A ruptured aneurysm or aortic dissection usually requires emergency surgery. If an aneurysm is discovered that is at risk of rupture, it may be repaired in a planned surgery. The type of surgery depends on the location of the aneurysm.

If an aneurysm is larger than 5–6 cm (2 in.) and is in the ascending aorta that leads from the heart toward the head or in the middle curved part of the aorta called the aortic arch, the aorta is usually replaced with a plastic or fabric graft. This is major surgery through the middle of the chest bone and requires a heart-lung machine.

If an aneurysm is in the descending thoracic aorta that extends downward and is more than 6 cm (2 in.), the aorta is replaced with a fabric graft. This is major surgery performed on the left side of the chest and possibly reaching to the abdomen. Sometimes endovascular stenting can be used for a descending thoracic aneurysm. This is a less invasive method that does not require cutting into the chest; rather, a tiny metal or plastic tube is inserted into the aorta to hold it open.

Prognosis

The prognoses for thoracic aortic aneurysms depend on the presence of other medical problems such as heart disease, hypertension, or diabetes. Aortic surgery carries the risk of serious complications, and 5%–10% of patients die soon after aortic surgery. Aneurysm stenting sometimes damages blood vessels supplying the leg, which may require a second surgery.

Thyroid hormone resistance syndrome

Definition

Thyroid hormone resistance syndrome refers to a disorder in which the individual’s body tissues have reduced responsiveness to the active form of thyroid hormone, triiodothyronine, or T3. Tissues respond when thyroid hormone receptors, which are proteins within cells, become activated by binding thyroid hormone. There are three

basic types of thyroid receptors (TRs): thyroid receptor alpha-1, most commonly found in heart and skeletal muscle; thyroid receptor beta-1, predominantly found in the brain, liver, and kidney; and thyroid receptor beta-2, primarily limited to the hypothalamus and the pituitary gland in the brain.

These thyroid hormone receptors are encoded by two different genes, *THRA* and *THRB*, respectively. The fact that the three major types of hormone receptors are found in different proportions in different organs explains why some body tissues (for example, tissues with normal alpha receptors) can show signs of thyroid hyperactivity while other tissues (for example, those with mutations in the beta receptors) may have features of thyroid underactivity.

Although thyroid hormone resistance syndrome has been recognized since 1967, it was only in the late 1980s that a mutation in the thyroid hormone receptor gene, beta (*THRB*) was discovered to be the cause of most cases of the disorder. Researchers identified both autosomal dominant and autosomal recessive forms of thyroid hormone resistance syndrome. More recently, in 2012 and 2013, geneticists began to see patients with thyroid resistance syndrome who lacked mutations in the *THRB* gene but did have mutations in the thyroid hormone receptor gene, alpha (*THRA*).

Description

Thyroid hormones and the thyroid feedback system

To understand the characteristic features of thyroid hormone resistance syndrome, it is helpful first to have an overview of the process of thyroid hormone secretion and activation. Under normal circumstances, the level of thyroid hormone in the bloodstream and body tissues is kept fairly constant by a feedback system. Secretion of thyroid hormone begins in the hypothalamus of the brain, a small structure located just above the brainstem. The hypothalamus secretes a hormone called thyrotropin-releasing hormone or TRH. TRH in return stimulates the release of thyroid-stimulating hormone (TSH) from the anterior lobe of the pituitary gland, which is located below the hypothalamus at the base of the brain. The pituitary gland in human adults is a small gland about the size of a pea.

Thyroid-stimulating hormone signals the thyroid gland itself to produce two forms of thyroid hormone: thyroxine or T4; and triiodothyronine or T3. The ratio of T4 to T3 is about 20 to 1. T4 is a prohormone—the relatively inactive precursor of T3, which is the form of thyroid hormone that is active in the body's target tissues. T4 is converted into T3 within the cells by various enzymes.

When the levels of T4 and T3 in the blood rise to a certain point, they inhibit the production of TSH in the pituitary gland, which in turn inhibits the release of the thyroid hormones from the thyroid gland. As the blood levels of the thyroid hormones drop, the pituitary gland begins to release more TSH, stimulating the thyroid gland to produce more thyroid hormones. The thyroid system is an example of a closed-loop feedback process.

Thyroid hormone resistance

In thyroid hormone resistance syndrome, mutations in either of the two genes that code for thyroid receptor proteins—*THRB* and *THRA*—impair the ability of the cells in the target tissues to take in the hormone across the cell membrane or to metabolize it. Patients identified with thyroid hormone resistance syndrome have a range of different signs and symptoms, depending on which thyroid receptor gene has a mutation and whether the inheritance pattern is autosomal dominant or autosomal recessive.

Genetic profile

About 85% of known cases of thyroid hormone resistance syndrome are associated with mutations in the *THRB* gene on the short arm of chromosome 3 at 3p24.2.

Thyroid hormone resistance, autosomal dominant, beta

Also known as generalized thyroid hormone resistance or GTHR, this form of the disorder is inherited in an autosomal dominant manner, which means that only one copy of the mutated gene is needed for the affected person to develop the characteristic features of the disorder. These may include goiter, abnormal patterns of bone growth and maturation, deafness, and an abnormally rapid heartbeat (tachycardia). The disorder is suspected when a thyroid function test indicates high levels of thyroxine and triiodothyronine in the bloodstream along with normal or slightly elevated levels of thyroid-stimulating hormone. This finding results from disruption of the normal thyroid feedback system in that the pituitary gland does not respond to the high levels of thyroid hormones in the blood but continues to produce TSH.

Thyroid hormone resistance, autosomal recessive, beta

Also known as Refetoff syndrome after its discoverer, this form of thyroid hormone resistance was the first one identified in 1967, although it was not then known to be caused by a genetic mutation. The signs and symptoms of this form of thyroid resistance syndrome are similar to those of the autosomal dominant form, with the exception of the fact that patients' laboratory test results indicate significantly

KEY TERMS

Adenoma—A benign tumor that develops in glandular tissue. A thyroid adenoma may produce large amounts of thyroid hormone that disrupt the normal thyroid feedback system.

Analogue—A drug or other chemical compound that resembles another in structure or constituents but has different effects.

Endocrine gland—Any gland that secretes its products directly into the bloodstream rather than through a duct. The hypothalamus, pituitary, and thyroid are all endocrine glands.

Euthyroid—Having normal thyroid gland function.

Exophthalmos—The bulging of the eye forward from the orbit. It is a symptom of abnormally high levels of thyroid hormone.

Goiter—A swelling of the neck or larynx caused by enlargement of the thyroid gland.

Hypothalamus—A structure in the brain just above the brainstem that secretes thyrotropin-releasing hormone (among other functions) to stimulate the pituitary gland.

Pituitary gland—An endocrine gland located at the base of the hypothalamus. The anterior portion of the pituitary gland secretes thyroid-stimulating hormone

(TSH) in response to thyrotropin-releasing hormone (TRH) from the hypothalamus. The pituitary gland is also called the hypophysis.

Prohormone—A precursor of a more active hormone. Thyroxine is the prohormone of triiodothyronine.

Receptor—A molecule in or on the surface of a cell that recognizes and binds with specific molecules, such as hormones, neurotransmitters, or drugs.

Tachycardia—An abnormally rapid heartbeat in an adult at rest (that is, not exercising), usually regarded as 100 beats per minute or faster.

Thyroid-stimulating hormone (TSH)—A hormone produced in the anterior lobe of the pituitary gland that stimulates the thyroid gland to produce thyroxine and triiodothyronine. It is also known as thyrotropin.

Thyrotropin-releasing hormone (TRH)—A hormone produced by the hypothalamus that stimulates the pituitary gland to release TSH.

Thyroxine (T4)—The major form of thyroid hormone circulating in the blood. It is converted in the liver and the thyroid gland itself into triiodothyronine, the most active thyroid hormone.

Triiodothyronine (T3)—The most active and final form of thyroid hormone.

elevated levels of thyroid-stimulating hormone as well as high levels of thyroxine and triiodothyronine.

Thyroid hormone resistance, alpha

This form of thyroid hormone resistance syndrome was first reported in 2012 and 2013 by two groups of researchers in the United Kingdom and the Netherlands. It is caused by mutations in the *THRA* gene on the long arm of chromosome 17 at 17q11.2 and is thought to be inherited in an autosomal dominant pattern. Patients with this mutation show delayed bone development, malformations of the skeleton, mental retardation, constipation, and anemia. Laboratory test results indicate low-to-normal levels of thyroxine; normal-to-high levels of triiodothyronine; an abnormally low T4 to T3 ratio; normal levels of thyroid-stimulating hormone; and anemia.

Demographics

Thyroid hormone resistance syndrome is rare worldwide, estimated to occur once in every 40,000 to 50,000 live births. About 3,500 cases had been reported worldwide as of 2015. The syndrome affects males and females

equally. As of 2015, it was also thought to affect all races and ethnic groups equally.

Signs and symptoms

Thyroid hormone resistance, autosomal dominant, beta

Patients with this form of thyroid hormone resistance syndrome may be euthyroid (showing normal thyroid gland function) along with a goiter (swelling in the neck) and high levels of thyroid hormone in the blood. The goiter results from the thyroid gland's extra production of thyroid hormones. Children with this form of thyroid hormone resistance syndrome may have delayed speech development and be diagnosed with attention-deficit hyperactivity disorder (ADHD). Patients with this form of the syndrome will respond to the administration of thyrotropin-releasing hormone or TRH.

Thyroid hormone resistance, autosomal recessive, beta

Patients with the autosomal recessive form of thyroid hormone resistance due to mutations in the *THRB* gene

typically have some symptoms of hyperthyroidism, including bulging eyes (exophthalmos) as well as goiter. Infants with this form of the syndrome are often small for their gestational age or may have a low birth weight at time of birth. They may also have hearing impairments.

Thyroid hormone resistance, alpha

Patients with this form of thyroid hormone resistance syndrome have abnormalities of skeletal growth, including unusually short stature and an abnormally large head (macrocephaly) with coarse facial features. They may show signs of hypothyroidism, including a low rate of metabolism and weight gain. Patients also have some gastrointestinal symptoms, most often constipation. Children may have relatively high birth weight, and mild or moderate mental retardation. Patients are also usually anemic and have high blood cholesterol levels.

Diagnosis

Thyroid hormone resistance syndrome can be diagnosed at almost any age, although thyroid function test results will be abnormal from birth. In older children and adults, the diagnosis of the various forms of thyroid hormone resistance syndrome begins with a patient history, including indications of mental retardation and such neurological symptoms as ADHD or delayed speech. The history-taking is followed by an office examination of the patient's facial features, heart rate, and skeletal abnormalities, if any. The next step is a thyroid function test: a blood test for the levels of the two thyroid hormones, the ratio between them, and the level of thyroid-stimulating hormone. A complete blood count will also be done to evaluate the patient for anemia.

If the results of the thyroid function test suggest the presence of thyroid hormone resistance, other tests will be performed to ensure that the abnormal levels of TSH are not caused by a thyroid-secreting adenoma in the pituitary gland. This type of adenoma is a slow-growing benign tumor in the pituitary gland that secretes excessive amounts of TSH. Two types of tests that are done to exclude a pituitary adenoma are an MRI of the patient's brain and a thyrotropin-releasing hormone test. This second test involves an initial test of the patient's blood hormone levels followed by an injection of TRH and a second blood test an hour later.

Lastly, the diagnosis can be confirmed by molecular genetic testing for mutations of the *THRB* and *THRA* genes. There were three laboratories (in Germany, Portugal, and the United States) that offered tests for mutations in the *THRA* gene as of 2015. There were 14 laboratories worldwide that offer testing for the autosomal dominant form of thyroid hormone resistance associated with mutations of

QUESTIONS TO ASK YOUR DOCTOR

- Which type of thyroid hormone resistance syndrome do I have?
- Will I need genetic testing, or will the results of a thyroid function test be adequate for a diagnosis?
- Which treatments will you recommend? What are their long-term side effects, if any?
- How likely am I to pass on my mutation to my children?

the *THRB* gene and seven laboratories that offer testing for the autosomal recessive form of the disorder.

Treatment and management

Treatment and management depends on the type of thyroid hormone resistance and the severity of the patient's symptoms. Some patients have abnormal blood test results but no external symptoms and do not need any treatment. Children, however, should be monitored to make sure that they are growing and developing at a normal rate.

Patients with mutations in the *THRA* gene were treated with levothyroxine tablets as of 2015. Levothyroxine is a synthetic form of T₄ and is converted in the patient's body to T₃, the active form of thyroid hormone. According to the researchers who first identified mutations in the *THRA* gene, therapy with levothyroxine brings the patients' blood levels of thyroid hormone back to normal and relieves constipation, but does not affect mental functioning or short stature.

Patients with tachycardia are treated with beta-blockers, a class of drugs that can slow the heartbeat in patients with abnormally high blood levels of thyroid hormone.

A drug known as tiratricol or TRIAC, which is an analogue of thyroid hormone, is used in the United Kingdom and France to treat thyroid hormone resistance syndrome. It is not, however, approved for sale in the United States and Canada because of its misuse in the late 1990s as a weight-loss aid. The Utah-based manufacturer agreed to stop distributing any product containing tiratricol in 2000.

Prognosis

Thyroid hormone resistance syndrome is not a life-threatening disorder and is not known to shorten patients' lifespans. Mutations in the *THRA* gene and the autosomal dominant form of thyroid resistance associated with *THRB* mutations can obviously have a severe impact on

a child's intellectual and social development as well as growth in height and physical coordination.

Because administration of synthetic thyroid hormone can affect an unborn child, women diagnosed with thyroid hormone resistance syndrome should consult their physician before they become pregnant, and should be carefully monitored throughout pregnancy.

Thyroid hormone resistance syndrome is known to increase the risk of osteoporosis in both males and females; thus adult patients diagnosed with the syndrome should have their bone density monitored.

Rebecca J. Frey, PhD

Tourette syndrome

Definition

Tourette syndrome is an inherited disorder of the nervous system characterized by a variable expression of unwanted movements and noises (tics).

X-ray of a 25-year-old man with Tourette syndrome, showing electrodes implanted in his brain to stimulate the thalamus in an attempt to improve the symptoms. (Zephyr/Science Source)

Description

The first references in the literature to what might today be classified as Tourette syndrome largely described individuals who were wrongly believed to be possessed by the devil. In 1885, Gilles de la Tourette, a French neurologist, provided the first formal description of this syndrome. He described the disorder as an inherited neurological condition characterized by motor and vocal tics.

Although vocal and motor tics are the hallmark of Tourette syndrome, other symptoms such as the expression of socially inappropriate comments or behaviors, obsessive-compulsive disorder, attention-deficit disorder, self-injuring behavior, depression, and anxiety also appear to be associated with Tourette syndrome. Most research suggests that Tourette syndrome is an inherited disorder, although a gene responsible for Tourette syndrome has not yet been discovered.

Genetic profile

The cause of Tourette syndrome is unknown, although some studies suggest that the tics associated with Tourette syndrome are caused by an increased amount of a neurotransmitter called dopamine. A neurotransmitter is a chemical found in the brain that helps to transmit information from one brain cell to another. Other studies suggest that the defect in Tourette syndrome involves another neurotransmitter called serotonin, or involves other chemicals required for normal functioning of the brain. It is clear that genetic factors are involved in the occurrence of Tourette syndrome because studies of

identical twins (twins who share all the same genes) show that about 85% of the time that one is affected, the other is also affected. One theory is that Tourette syndrome is an autosomal dominant disorder with decreased penetrance. This theory has not been proven and may not be true in all families. An autosomal dominant disorder results from a change in one copy of a pair of genes. Individuals with an autosomal dominant disorder have a 50% chance of passing on the changed gene to their children. Decreased penetrance means that not all people who inherit the changed gene will develop symptoms. There is some evidence that females who inherit the Tourette syndrome gene have a 70% chance of exhibiting symptoms, and males have a 99% chance of having symptoms.

Other theories about the cause of Tourette syndrome include the presence of a single gene in combination with other genetic or environmental changes that cause the condition. Some studies have indicated that it is unlikely that there is one genetic change alone that is responsible for causing Tourette syndrome. It is possible that Tourette syndrome has different causes in different individuals. Linkage analysis has been performed by several researchers to identify genes that may be associated with Tourette syndrome. In linkage analysis, researchers determine if people with Tourette syndrome have more markers (identifiable DNA sequences) associated with particular genes in common than would be expected by chance. These studies have indicated several chromosomal locations of interest, including locations on chromosome 2, 4, 5, 7, 8, 10, 11, 13, 17, and 19. In addition, individuals with Tourette syndrome features from different families have been reported to have chromosomal rearrangements that involve chromosome breaks in chromosomes 2, 6, 8, 7, and 18q. The areas where the chromosome broke in these families are under further investigation. More research is needed to establish the cause of Tourette syndrome.

Researchers are also interested in determining if the sex of the parent passing on a particular genetic change for Tourette syndrome influences the occurrence or severity of symptoms. Researchers also want to determine how having a family history of Tourette syndrome in both parents affects the chance for, and the severity of, the condition in their children.

Demographics

Tourette syndrome is found in all populations and all ethnic groups, but is three to four times more common in males than in females and is more common in children than in adults. The exact frequency of Tourette syndrome is unknown, but estimates range from 1 to 10 in 1,000 children or adolescents.

Signs and symptoms

Motor and vocal tics

The principal symptoms of Tourette syndrome include simple and complex motor and vocal tics. Simple motor tics are characterized by brief muscle contractions of one or more limited muscle groups. An eye twitch is an example of a simple motor tic. Complex motor tics tend to appear more complicated and purposeful than simple tics and involve coordinated contractions of several muscle groups. Some examples of complex motor tics include the act of hitting oneself and jumping. Copropraxia, the involuntary display of unacceptable/obscene gestures, and echopraxia, the imitation of the movement of another individual, are other examples of complex motor tics.

Vocal tics are actually manifestations of motor tics that involve the muscles required for vocalization. Simple vocal tics include stuttering, stammering, abnormal emphasis of part of a word or phrase, and inarticulate noises such as throat clearing, grunts, and high-pitched sounds. Complex vocal tics typically involve the involuntary expression of words. Perhaps the most striking example of this is coprolalia, the involuntary expression of obscene words or phrases, which occurs in less than one-third of people with Tourette syndrome. The involuntary echoing of the last word, phrase, sentence, or sound vocalized by oneself (phalilalia) or of another person or sound in the environment (echolalia) are also classified as complex tics.

The type, frequency, and severity of tics exhibited vary tremendously between individuals with Tourette syndrome. Tourette syndrome has a variable age of onset, and tics can start anytime between infancy and age 18. Initial symptoms usually occur before the early teens, and the mean age of onset for both males and females is approximately seven years of age. Most individuals with symptoms initially experience simple muscle tics involving the eyes and the head. These symptoms can progress to tics involving the upper torso, neck, arms, hands, and occasionally the legs and feet. Complex motor tics are usually the latest-onset muscle tics. Vocal tics usually have a later onset than motor tics. In some rare cases, people with Tourette syndrome suddenly present with multiple, severe, or bizarre symptoms. Not only is there extreme variability in clinical symptoms between individuals with Tourette syndrome, but individuals commonly experience a variability in type, frequency, and severity of symptoms within the course of their lifetime. Adolescents with Tourette syndrome often experience unpredictable and variable symptoms, which may be related to fluctuating hormone levels and decreased compliance in taking medications. Adults often experience a decrease in symptoms or a complete end to symptoms.

A number of factors appear to affect the severity and frequency of tics. Stress appears to increase the frequency and severity of tics, while concentration on another part of the body that is not taking part in a tic can result in the temporary alleviation of symptoms. Relaxation, following attempts to suppress the occurrence of tics, may result in an increased frequency of tics. An increased frequency and severity of tics can also result from exposure to drugs such as steroids, cocaine, amphetamines, and caffeine. Hormonal changes such as those that occur prior to the menstrual cycle can also increase the severity of symptoms.

Other associated symptoms

People with Tourette syndrome are more likely to exhibit nonobscene, socially inappropriate behaviors such as expressing insulting or socially unacceptable comments or socially unacceptable actions. It is not known whether these symptoms stem from a more general dysfunction of impulse control that might be part of Tourette syndrome.

Tourette syndrome appears to also be associated with attention-deficit disorder (ADD). ADD is a disorder characterized by a short attention span and impulsivity and, in some cases, hyperactivity. Researchers have found that 21%–90% of individuals with Tourette syndrome also exhibit symptoms of ADD, whereas 2%–15% of the general population exhibit symptoms of ADD.

People with Tourette syndrome are also at higher risk for having symptoms of obsessive-compulsive disorder (OCD). OCD is a disorder characterized by persistent, intrusive, and senseless thoughts (obsessions) or compulsions to perform repetitive behaviors that interfere with normal functioning. A person with OCD, for example, may be obsessed with germs and may counteract this obsession with continual hand washing. Symptoms of OCD are present in 1.9%–3% of the general population, whereas 28%–50% of people with Tourette syndrome have symptoms of OCD.

Self-injurious behavior (SIB) is also seen more frequently in those with Tourette syndrome. Approximately 34%–53% of individuals with Tourette syndrome exhibit some form of self-injuring behavior. The SIB is often related to OCD, but can also occur in those with Tourette syndrome who do not have OCD.

Symptoms of anxiety and depression are also found more commonly in people with Tourette syndrome. It is not clear, however, whether these symptoms are symptoms of Tourette syndrome or occur as a result of having to deal with the symptoms of moderate to severe Tourette syndrome.

People with Tourette syndrome may also be at increased risk for having learning disabilities and personality disorders and may be more predisposed to behaviors such as aggression, antisocial behaviors, severe temper

KEY TERMS

Attention-deficit disorder (ADD)—Disorder characterized by a short attention span, impulsivity, and, in some cases, hyperactivity.

Autosomal dominant—A pattern of genetic inheritance where only one abnormal gene is needed to display the trait or disease.

Coprolalia—The involuntary expression of obscene words or phrases.

Copropexia—The involuntary display of unacceptable/obscene gestures.

Decreased penetrance—Individuals who inherit a changed disease gene, but do not develop symptoms.

Dysphoria—Feelings of anxiety, restlessness, and dissatisfaction.

Echolalia—Involuntary echoing of the last word, phrase, or sentence that is spoken by someone else or by sounds in the environment.

Echopraxia—The imitation of the movement of another individual.

Linkage analysis—A type of genetic study used to identify genes that cause specific diseases.

Neurotransmitter—Chemical in the brain that transmits information from one nerve cell to another.

Obsessive-compulsive disorder (OCD)—Disorder characterized by persistent, intrusive, and senseless thoughts (obsessions) or compulsions to perform repetitive behaviors that interfere with normal functioning.

Phalilalia—Involuntary echoing of the last word, phrase, sentence, or sound vocalized by oneself.

Tic—Brief and intermittent involuntary movement or sound.

outbursts, and inappropriate sexual behavior. Further controlled studies need to be performed, however, to ascertain whether these behaviors are symptoms of Tourette syndrome. Individuals with Tourette syndrome are more likely to get migraine headaches and to have sleep disorders, such as difficulty falling asleep, staying asleep, or having unusual movements during sleep.

Diagnosis

Tourette syndrome cannot be diagnosed through a blood test. The diagnosis is made through observation

and interview of the patient and discussions with other family members. The diagnosis of Tourette syndrome is complicated by a variety of factors. The extreme range of symptoms of this disorder makes it difficult to differentiate Tourette syndrome from other disorders with similar symptoms. Diagnosis is further complicated by the fact that some tics appear to be within the range of normal behavior. For example, an individual who only exhibits tics such as throat clearing and sniffing may be misdiagnosed with a medical problem such as allergies. In addition, bizarre and complex tics such as coprolalia may be mistaken for psychotic or “bad” behavior. Diagnosis is also confounded by individuals who attempt to control tics in public and in front of healthcare professionals and deny the existence of symptoms. Although there is disagreement over what criteria should be used to diagnose Tourette syndrome, one aid in the diagnosis is the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5). The DSM-5 outlines suggest diagnostic criteria for a variety of conditions, including Tourette syndrome, such as:

- Presence of both motor and vocal tics at some time during the course of the illness.
- The occurrence of multiple tics nearly every day through a period of more than one year, without a
- remission of tics for a period of greater than three consecutive months.
- Symptoms cause distress or impairment in functioning.
- Age of onset prior to 18 years of age.
- The symptoms are not due to medications or drugs and are not related to another medical condition.

Some physicians critique the DSM-IV criteria, citing that they do not include the full range of behaviors and symptoms seen in Tourette syndrome. Others criticize the criteria since they limit the diagnosis to those who experience a significant impairment, which may not be true for individuals with milder symptoms. For this reason, many physicians use their clinical judgment as well as the DSM-IV criteria as a guide to diagnosing Tourette syndrome.

Treatment and management

There is no cure for Tourette syndrome, and treatment involves the control of symptoms through educational and psychological interventions, behavioral training, and/or medications. The treatment and management of Tourette syndrome vary from patient to patient and should focus on the alleviation of the symptoms that are most bothersome to the patient or that cause the most interference with daily functioning.

QUESTIONS TO ASK YOUR DOCTOR

- Would my child benefit from psychotherapy?
- What side effects could result from taking Ritalin and Clonidine?
- Are there early signs of medication side effects?
- What educational interventions do you recommend?

Psychological and educational interventions

Psychological treatments such as counseling are not generally useful for the treatment of tics, but can be beneficial in the treatment of associated symptoms such as obsessive-compulsive behavior and attention-deficit disorder. Counseling may also help individuals to cope better with the symptoms of this disorder and to have more positive social interactions. Psychological interventions may also help people cope better with stressors that can normally be triggers for tics and negative behaviors. The education of family members, teachers, and peers about Tourette syndrome can be helpful and may foster acceptance and prevent social isolation.

Behavioral training

A variety of behavioral training techniques has been suggested and tried in people with Tourette syndrome. Some of these include conditioning techniques (training a person to respond to a particular stimulus with a particular behavior), awareness training, biofeedback training (learning how to control one's involuntary nervous system), and habit reversal. Relaxation therapies have been tried with short-term success. The effectiveness of behavioral training as a whole is not clear.

Medications

Many people with mild symptoms of Tourette syndrome never require medications. Those with severe symptoms may require medications for all or part of their lifetime. The most effective treatment of tics associated with Tourette syndrome involves the use of drugs such as Haloperidol, pimozide, sulpiride, and tiapride, which decrease the amount of dopamine in the body. Unfortunately, the incidence of side effects, even at low dosages, is quite high. The short-term side effects can include sedation, dysphoria, weight gain, movement abnormalities, depression, and poor school performance. Long-term side effects can include phobias, memory difficulties, and

personality changes. These drugs are therefore better candidates for short-term rather than long-term therapy.

Tourette syndrome can also be treated with other drugs such as clonidine, clonazepam, and risperidone, but the efficacy of these treatments is unknown. In many cases, treatment of associated conditions such as ADHD and OCD is often more of a concern than the tics themselves. Clonidine used in conjunction with stimulants such as Ritalin may be useful for treating people with Tourette syndrome who also have symptoms of ADHD. Stimulants should be used with caution in individuals with Tourette syndrome since they can sometimes increase the frequency and severity of tics. OCD symptoms in those with Tourette syndrome are often treated with drugs such as Prozac, Luvox, Paxil, and Zoloft.

In many cases, the treatment of Tourette syndrome with medications can be discontinued after adolescence. Trials should be performed through the gradual tapering-off of medications and should always be done under a doctor's supervision.

Surgical treatments

Several areas of the brain have been targeted for surgical approaches to the treatment of severe tic disorders. In addition, deep brain stimulation (using sound waves to stimulate certain areas of the brain) has been suggested as treatment, as there has been some success with this treatment in other movement disorders. Clinical trials are needed to determine the effectiveness and safety of this treatment for possible use in the future.

Prognosis

The prognosis for Tourette syndrome in individuals without associated psychological conditions is often quite good, and only approximately 10% of people with Tourette syndrome experience severe tic symptoms. Approximately 46% of individuals with Tourette syndrome will experience a decrease in the frequency and severity of tics, and another 26% will experience a complete end of symptoms by late adolescence. Fourteen percent will have no change and 14% will have an increase in symptoms. There does not appear to be a definite correlation between the type, frequency, and severity of symptoms and the eventual prognosis. Patients with severe tics may experience social difficulties and may isolate themselves from others for fear of shocking and embarrassing them. People with Tourette syndrome who have other symptoms such as obsessive-compulsive disorder, attention-deficit disorder, and self-injurious behavior usually have a poorer prognosis.

Treacher Collins syndrome

Definition

Treacher Collins syndrome (TCS) is a genetic disorder involving abnormal facial development. Individuals with TCS have underdevelopment of the jawbone, cheekbones, ears, and eye area. These features range widely from mild to severe. Intelligence and lifespan are usually normal.

Description

TCS was first described by E. Treacher Collins in 1900 after observation of two individuals with similar facial abnormalities. In 1949, Franceschetti and Klein gave TCS another name, mandibulofacial dysostosis. TCS is also sometimes called Franceschetti-Kleinsyndrome or Franceschetti syndrome.

The features of TCS result from a problem in early embryonic development. After an embryo forms, there are cells that are unspecialized and have the ability to develop into any type of cell in any part of the body (neural crest cells). Early in development, the neural crest cells travel to different areas of the embryo and specialize to become a specific type of cell for a specific organ or body part. The branchial arches are the areas where neural crest cells specialize to develop the bone structure and features of the face. In individuals with TCS there is thought to be an error in the movement of the neural crest cells to the branchial arches or in the specialization of those cells once they reach the branchial arches. The result is underdevelopment of the facial bones, eyes, and ears.

Individuals with mild features of TCS may go undiagnosed. Sometimes adults do not know they have TCS until they have a child with more noticeable features. This can cause feelings of guilt for the parent. Children with

The ear and hearing aid of Lidia DiFrancesco, a woman affected by Treacher Collins syndrome. She was born with no chin, cheekbones, or ears; she also had small, droopy eyes and her jaw was too far back. She was deaf, had no tear ducts, and could hardly breathe. She underwent 20 surgeries including rib grafts to create ears and a scalp graft to make cheekbones. (James Ambler/Barcroft Media/Getty Images)

KEY TERMS

Coloboma—An abnormality on the upper or lower eyelid that often gives the lid a droopy appearance.

Craniofacial—Relating to or involving both the head and the face.

Tracheostomy—An opening surgically created in the trachea (windpipe) through the neck to improve breathing.

more moderate to severe features of TCS look strikingly different and may be teased or shunned. These children are at risk for psychological stress and low self-esteem. Even adults with TCS who are productive and successful may battle issues of social stigma and low self-esteem regarding their facial differences.

Genetic profile

TCS is an autosomal dominant condition. Children of an affected parent have a 50% chance of inheriting the disorder. Males and females are affected equally. The severity of symptoms ranges widely, even among members of the same family. Therefore, the severity of a child's features cannot be predicted by the features of the affected parent.

About 40% of babies born with TCS have one affected parent. The other 60% are assumed to have a new, sporadic gene mutation (alteration). If a child has a new mutation (one that is not carried by the parents) then his or her siblings will have an extremely low chance of also having TCS. When a baby with TCS is born to seemingly normal parents, it is important to examine both parents carefully for mild features of TCS in order to give them accurate recurrence risks.

The gene for TCS is on chromosome 5 and is called *TCOF1*. This gene produces a protein that has been named treacle. Disease-causing *TCOF1* mutations result in absent or inactive treacle. The exact role of treacle is not known but it is thought to be involved in early embryo neural crest cell movement or specialization in the branchial arches.

Demographics

TCS is rare and affects an estimated 1 in 25,000 to 50,000 live births.

Signs and symptoms

TCS is described as a craniofacial condition because its features are all related to the head and face. The overall

head size may be smaller than average (microcephaly). The outer corners of the eyes slant downward. There may be colobomas on the lower eyelids, giving the lids a droopy appearance. The bridge of the nose is usually wide. Most individuals with TCS have underdeveloped cheekbones (malar bones), which give that area of the face a flat or sunken appearance. The lower jaw and chin are usually small and retroverted (jawbone points downward toward the neck instead of pointing out perpendicular to the neck). Many individuals also have a large mouth. Cleft palate (with or without cleft lip) is seen in one-quarter to one-third of patients with TCS.

Ear abnormalities are also common in TCS. The ears may be low-set, small, misshapen, or absent. For this reason, hearing loss or deafness is a common feature of TCS. The hearing loss is usually due to abnormalities in the middle ear structures rather than the outer ear structures.

Infants with moderate or severe malar bone underdevelopment may have compressed airways. These babies can have problems breathing after birth and may need a respirator or tracheostomy. A small, retroverted jaw and chin can cause feeding problems that may warrant a feeding tube.

The severity of features present at birth remains constant throughout life. TCS does not get progressively better or worse as an individual ages.

Diagnosis

The diagnosis of TCS is usually made by physical examination and identification of the typical facial features. Computerized tomography (CT) scans can be used to determine the degree of underdevelopment of the facial bone structure.

There are other syndromes that have facial appearances that resemble TCS. A complete physical examination of other body systems can help to establish a diagnosis of TCS. TCS can be distinguished from Nager syndrome and Miller syndrome if no abnormalities are present in the hands or arms. TCS can be distinguished from oculoauriculovertebral (OAV) conditions (for example, Goldenhar syndrome) because facial involvement is bilateral (affecting both sides of the face) and the spinal column is normal.

If there are several people in a family with TCS, genetic linkage studies can be performed. Linkage studies require blood samples from many family members, both affected and unaffected. Markers on the *TCOF1* gene are analyzed and compared to determine which gene version is shared by affected family members. The disease-causing gene should be present in all affected family members and absent from all unaffected members. Linkage studies can be performed on an unborn baby to

QUESTIONS TO ASK YOUR DOCTOR

- Do you have any suggestions regarding plastic surgery?
- At what specific points in my child's life should the surgeries be performed?
- What are the risks versus benefits of the surgeries?
- Do you recommend that my child undergo a hearing evaluation?

determine if the baby inherited the family's disease-causing gene. Prenatal ultrasound can also be used to look for facial features of TCS. While there have been reports of prenatal diagnosis of TCS with ultrasound only, babies with mild features may appear normal. Detection may also depend on the skill of the physician performing the ultrasound and his or her experience with features of TCS.

Treatment and management

Newborn infants with severe TCS may require a ventilator, tracheostomy, or feeding tube if life-threatening breathing or feeding problems exist. A cleft palate can be repaired with surgery. Hearing aids can help individuals with hearing loss.

For most individuals, the problems of TCS are largely cosmetic. Plastic surgery can help to rebuild the bone structure of the face, which may improve appearance as well as breathing and feeding. Surgeons can use bone grafts to build up the underdeveloped cheekbones. The jawbone can be "lengthened" and its angle repositioned. The bridge of the nose can be narrowed. Ears can be reconstructed using cartilage from the ribcage. Surgery can also be performed on the eye area.

This reconstruction may take multiple surgeries at different ages. Each individual must be evaluated for his or her unique features and needs. Surgeries are timed with facial growth and emotional needs and maturity of the patient.

Prognosis

A small percentage of newborns with TCS will have life-threatening breathing difficulties, and infant deaths can occur. However, the majority of individuals with TCS have a normal lifespan.

Trichorhinophalangeal syndrome

Definition

Trichorhinophalangeal syndrome, or Langer-Giedion syndrome (LGS), is characterized by skeletal abnormalities and dysmorphic (distinctive) facial features. Most people with LGS also have intellectual disability.

Description

LGS affects mostly the skeletal system and facial structure. Since the features include abnormalities in the hair (tricho), nose shape (rhino), and fingers and toes (phalangeal), the technical name for LGS is trichorhinophalangeal syndrome.

Genetic profile

LGS is not usually passed through generations in a family. However, the condition is considered a contiguous-gene syndrome. This means that it is caused by the loss of functional copies of two genes near each other on chromosome 8. Research suggests that another gene may be involved. Genetic counseling is suggested for anyone considering pregnancy who has a relative with this condition.

Demographics

About 50 cases of Langer-Giedion syndrome have been reported in the literature. Males are affected three times more often than females.

Signs and symptoms

Craniofacial features associated with Langer-Giedion syndrome include a bulbous, pear-shaped nose; a small jaw; a thin upper lip; and large ears. The hair is usually sparse, and the head is small in 60% of individuals with LGS. Mild to severe intellectual disability is present in 70% of people; it often affects speech more than other skills.

Skeletal features include exostoses—spiny growths on the bone—which occur before age five and usually increase in number until the skeleton matures. Compression of nerves or blood vessels, asymmetric limb growth, and limitation of movement are problems that can result from the exostoses. Scoliosis—a curvature of the spine—is found in some people, as well as thin ribs. Short stature is often seen as a result of epiphyses—cone-shaped bone ends. Longitudinal bone growth appears to be slowed. Short and/or curved fingers are common. Loose skin often occurs, but that tends to improve with age.

Features of LGS that are less commonly seen include loose joints and low muscle tone. Others are wandering eye (exotropia), droopy eyelid, widely spaced eyes, fractures in the bones, birthmarks that increase with age, hearing loss, heart or genito-urinary abnormalities, and webbing of the fingers.

Diagnosis

The criteria for diagnosis of LGS are a bulbous, pear-shaped nose and epiphyses and exostoses. These signs are probably all related to abnormal bone growth, but researchers do not yet understand the link to intellectual disability and hair abnormalities. The distinctive facial features may be recognized at birth. Changes in the epiphyses are recognizable through x-ray by age three, and exostoses are visible by age five. Chromosome

KEY TERMS

Contiguous gene syndrome—A genetic syndrome caused by the deletion of two or more genes located next to each other.

Craniofacial—Relating to or involving both the head and the face.

Epiphysis—The end of long bones, usually terminating in a joint.

Exostose—An abnormal growth (benign tumor) on a bone.

Intellectual disability—Significant impairment in intellectual function and adaptation in society. Usually associated with an intelligence quotient (IQ) below 70.

Philtrum—The center part of the face between the nose and lips that is usually depressed.

Short stature—Shorter than normal height; can include dwarfism.

analysis will likely reveal an abnormality in a certain region of chromosome 8.

There are no reports of prenatal diagnosis of this condition. To provide accurate genetic counseling regarding prognosis and risk of recurrence, it is important to distinguish this condition from others that are similar to it, such as trichorhinophalangeal syndrome, type 1.

Treatment and management

The treatment for LGS is tailored to each person. Exostoses may need to be surgically removed if they are causing problems with nerves or blood vessels. If the two leg lengths are different, corrective shoes may be helpful. Orthopedic devices such as braces or, more rarely, surgery may be indicated in severe cases of skeletal abnormality. Plastic surgery to alter specific features, such as the ears or nose, has been chosen by some people.

The risk of cancer at the site of the exostoses is not known but may be higher.

Special education for mentally retarded individuals is indicated. A focus on speech development may be appropriate.

Prognosis

Langer-Giedion syndrome does not alter lifespan. Complications from associated abnormalities such as intellectual disability, however, can cause problems. Asymmetry of the limbs can interfere with their function

and cause pain. Psychological effects due to physical abnormalities may also be experienced.

Triosephosphate isomerase deficiency

Definition

Triose phosphate isomerase (TPI) deficiency is a rare non-sex-linked (autosomal) disorder that is a result of an insufficient amount of the enzyme triose phosphate isomerase. This disorder is inherited as an autosomal recessive trait and is known to be caused by homozygous or compound heterozygous mutations in the *TPII* gene.

Description

Triose phosphate isomerase is an enzyme involved in the breakdown of glucose into the energy required to sustain cellular metabolism. Glucose is first converted into

the chemical pyruvate. Pyruvate then enters the tricarboxylic acid cycle (TCA cycle) to produce ATP, the chemical form of energy used by the cells. Glucose is broken down to the chemical pyruvate via a chemical pathway that involves 10 enzymes. TPI is the fifth enzyme in this reaction chain. The two major products of the reaction proceeding the TPI reaction are D-glyceraldehyde-3-phosphate (GAP) and dihydroxyacetone phosphate (DHAP). These two chemicals are isomers, which means that they have the same chemical formulas but different chemical structures. TPI is the enzyme that converts DHAP into GAP. This conversion (isomerization) is important because only GAP is used in the subsequent steps in the reaction pathway to the essential pyruvate molecules.

Under normal physiological conditions, DHAP is produced in much greater quantities than GAP (approximately 20:1). Therefore, it is essential that TPI convert the DHAP to GAP to increase the overall efficiency of pyruvate production from glucose. Individuals affected with TPI deficiency have extremely low levels of TPI activity because the enzyme that they do produce is not properly formed and, thus, is highly inefficient.

Genetic profile

The gene that is responsible for the production of TPI has been localized to a region on chromosome 12. There are many different mutations in this gene that lead to TPI deficiency. In every case, very slight changes in the chemical structure of TPI occur such that the TPI produced is less effective than a normal TPI molecule, especially when the body is hot, either from the weather or from exercise.

Demographics

TPI deficiency is extremely rare. As of 2015, approximately 40 cases had been reported. The documented rarity of this disorder does not seem to coincide with the observed frequency of reduced TPI activity in the population.

In a 1996 study of unselected individuals of Caucasian and Japanese descent, a Japanese researcher found that approximately 5 out of every 1,000 individuals had TPI activity that was only half of the normal TPI activity. In a separate study, it was estimated that 9 in 1,713 Caucasians and 7 in 168 African Americans showed these low levels of TPI activity. One possible explanation is that complete TPI deficiency is an embryo-lethal condition. In other words, if complete TPI deficiency is inherited at conception, the embryo is miscarried before the mother even knows that conception has occurred.

All of the mutations in the gene responsible for the production of TPI are expressed as recessive traits. This

KEY TERMS

Anemia—A blood condition in which the level of hemoglobin or the number of red blood cells falls below normal values. Common symptoms include paleness, fatigue, and shortness of breath.

Jaundice—Yellowing of the skin or eyes due to excess of bilirubin in the blood.

Thermolabile—Heat-sensitive. A thermolabile protein is a protein that easily loses its shape when heated even only slightly.

Transversion—A genetic term referring to a specific substitution of one base pair for another. There are only four possible transversions: guanine for cytosine, cytosine for guanine, adenine for thymine, or thymine for adenine.

Triose phosphate isomerase—Abbreviated TPI, this is the enzyme responsible for the conversion of dihydroxyacetone phosphate (DHAP) into D-glyceraldehyde-3-phosphate (GAP). DHAP and GAP are the two major products of a step in the multi-step process that converts glucose into ATP to supply the body with the energy it needs to sustain itself. Only GAP can continue in this process, but DHAP is produced in much higher quantities. People with TPI deficiency cannot change DHAP into GAP as efficiently as unaffected people, resulting in insufficient amounts of ATP from glucose to maintain normal cell function.

means that a child will inherit a mutation on the TPI1 gene from both parents. Also, if one child has been born affected with TPI deficiency, the likelihood that a second child of the same parents will also be affected is 25%.

Signs and symptoms

TPI deficiency affects primarily the circulatory and nervous systems. Disorders of the circulatory system include at least four separate forms of anemia (a lack of properly functioning red blood cells) that cause a lack of oxygen transport to the tissues and organs of the body. Disorders of the neurologic system include developmental delay and degenerative neurologic disorder with spasticity, a condition in which the nervous system progressively degenerates and the affected person suffers from spasticity similar to that seen in people with multiple sclerosis. Because of the malformations of the red blood cells in TPI deficiency affected individuals, the liver, the organ that is responsible for cleaning the blood, often becomes overworked. This causes jaundice (an

QUESTIONS TO ASK YOUR DOCTOR

- What supportive measures can I offer my child?
- Have there been any advancements in transfusion research?
- How feasible is an enzyme replacement?
- How often should my child's blood be tested?

abnormal yellowing of the skin and the whites of the eyes). Heart failure is also quite common and is often the cause of death in TPI deficiency patients.

People affected with TPI deficiency are generally highly susceptible to recurrent infections. This tendency is believed to be due to a depression of the immune system caused by improper blood function.

Diagnosis

If a family history of the disease leads to suspicion, TPI deficiency can be detected prenatally by a test of umbilical cord blood. A device recognized by the Food and Drug Administration is available to measure the activity of TPI on red blood cells taken in a sample. This device provides a definitive test for TPI deficiency. A blood test indicating extremely elevated levels of DHAP is also indicative of TPI deficiency.

Another blood test that can be performed is an autohemolysis test. This test allows TPI deficiency to be differentially diagnosed from certain other enzymatic deficiencies. In this test, samples of blood are drawn and incubated at body temperature for 48 hours. After this time, the amount of breakdown of the red blood cells is recorded. One sample is left untreated, one sample has added glucose, and a third sample has added ATP. If the untreated sample shows higher than normal breakdown of the red blood cells but those samples treated with glucose or ATP show a lessened breakdown of red blood cells, this is indicative of TPI deficiency. If glucose, but not ATP, slows the breakdown of the red blood cells, this indicates a diagnosis of G6PD deficiency. If ATP, but not glucose, slows the breakdown of the red blood cells, this indicates a diagnosis of pyruvate kinase deficiency. G6PD and pyruvate kinase are two other enzymes involved in the breakdown of glucose to pyruvate to ATP.

Treatment and management

No treatment is currently available for TPI deficiency. Studies are ongoing to determine the feasibility

of bone marrow transplants and enzyme replacement therapies. In 1999, TPI deficiency was corrected in a four-year-old boy by an enzyme replacement blood transfusion treatment. However, due to the temporary nature of the observed corrections in the biochemistry, it was concluded that a sustained reversal of the symptoms of TPI deficiency would require a continuous delivery of an active form of the TPI enzyme.

Prognosis

Individuals with TPI deficiency generally do not live past childhood. Enzyme replacement therapy and/or bone marrow transplantation may eventually prove to be effective means of treating TPI deficiency and improve survival rates for this rare genetic disorder.

Triple X syndrome

Definition

Triple X syndrome is a chromosomal disorder resulting from the presence of an extra X chromosome that can cause mild learning disabilities, tall statures, and psychiatric problems. Many women with triple X syndrome have no symptoms or complications from this condition.

Description

Triple X syndrome is also called triplo-X syndrome, trisomy X, XXX syndrome, and 47,XXX syndrome. Many women with this syndrome have no physical characteristics or intellectual differences because of it. Others have very mild differences, and a small minority of women with triple X syndrome can have more pronounced symptoms and signs of this condition.

Learning disabilities are more common in girls with triple X than in the general population. Women with triple X syndrome have an average IQ in the 85–90 range, compared to normal IQ of about 100. However, there is considerable variability in cognitive abilities, including IQs above normal for some affected girls. Many children with triple X require speech therapy in childhood, and they may reach both speech and motor milestones slightly later than their unaffected siblings. In adolescence, psychological problems such as depression or conduct disorder may be somewhat more common in girls with triple X, although this may be due to the environment in which the girls live more than the physical effects of triple X syndrome.

Triple X is not associated with abnormal physical characteristics, although girls with triple X are slightly taller (by approximately 4 inches, on average) than their siblings. Triple X is associated with normal puberty and fertility, and women with this condition are not at an increased risk to have children with chromosome

Human karyotype of Triple X syndrome. (Zuzana/Shutterstock)

abnormalities. Premature ovarian failure has been reported in some women with triple X syndrome.

Genetic profile

Triple X syndrome is caused by the presence of an extra X chromosome. Chromosomes are packages of genetic information that are present in every cell of the body. They come in pairs and humans have a total of 46 chromosomes, arranged into 23 pairs. The first 22 pairs of chromosomes are called “autosomes” and are numbered 1 to 22, from largest to smallest. The 23rd pair is called the “sex chromosomes.” Females typically have two X chromosomes (46,XX), and males have one X chromosome and one Y chromosome (46,XY). Triple X syndrome results from an extra copy of the X chromosome in each of a female’s cells. As a result of the extra X chromosome, each cell has a total of 47 chromosomes (47,XXX) instead of the usual 46. Women with triple X syndrome have three X chromosomes for a total of 47 chromosomes. Triple X syndrome occurs when there is an error in chromosome division, called nondisjunction, that occurs before conception in either the mother’s egg or the father’s sperm. This error occurs randomly; Triple X syndrome is not an inherited disorder.

Demographics

Approximately 1 in 1,000 women has triple X syndrome. This condition is underdiagnosed because of a lack of identifiable physical features. Only women are affected by triple X syndrome.

Signs and symptoms

The symptoms of this condition include the following:

- tall stature
- learning disabilities
- motor delays
- speech and language delay
- premature ovarian failure
- psychological problems

Diagnosis

Tests

Triple X syndrome is diagnosed by karyotype testing. A karyotype is a chromosome analysis that can be done on a blood sample or tissue obtained via prenatal diagnosis testing. A karyotype looks at the structure and number of a person’s chromosomes. The diagnosis of triple X syndrome is made if an extra X chromosome is present.

KEY TERMS

Chromosome—Organized package of genetic information contained in every cell of the human body. Most people have 46 chromosomes. Individuals with triple X syndrome have an extra X chromosome and 47 chromosomes total.

Karyotype—A karyotype is a picture of all the chromosomes from an individual’s cells. A karyotype also is a test used to check for chromosome abnormalities and is the diagnostic test for triple X syndrome.

Nondisjunction—An error in chromosome separation that occurs during cell division resulting in a woman receiving an extra X chromosome, leading to triple X syndrome.

Trisomy—The occurrence of an extra chromosome in a human. Women with triple X syndrome have an extra X chromosome. This is sometimes written as 47,XXX.

Most cases of triple X syndrome are diagnosed during pregnancy in mothers who have elected to have prenatal testing such as amniocentesis or chorionic villus sampling (CVS) for reasons unrelated to triple X syndrome. Prospective parents should meet with a geneticist or genetic counselor to discuss the diagnosis of triple X syndrome if this condition is diagnosed during a pregnancy. Because of its lack of physical findings and mild symptoms, triple X syndrome is underdiagnosed in the general population.

Treatment and management

Traditional

Because of the possible psychiatric issues and learning disabilities children with triple X syndrome may experience, it is important that girls with triple X syndrome be raised in a stable and supportive environment. The symptoms of this condition—especially learning disabilities and psychiatric problems—should be treated promptly.

There is no cure for triple X syndrome and treatment is based upon symptoms. The therapies for the symptoms of triple X syndrome are no different than the therapies that someone without triple X syndrome, but with the same symptoms, would receive. Individuals with symptoms due to triple X syndrome may receive speech therapy for speech delay, physical therapy for motor problems, and treatment for learning disabilities. In addition, they may receive treatment and counseling for psychiatric conditions if they develop this complication.

QUESTIONS TO ASK YOUR DOCTOR

- What are the karyotype results?
- What does this mean for my child?
- What should I do for my child?

Prognosis

The prognosis for women with triple X syndrome is very good. They live a normal lifespan and there are no physical abnormalities or intellectual disabilities associated with this condition.

Triploidy

Definition

Triploidy is a rare, lethal chromosome abnormality caused by the presence of an entire extra set of

chromosomes. A fetus with triploidy has 69 chromosomes, rather than 46. The majority of fetuses with triploidy are spontaneously miscarried during pregnancy. Those that survive until birth will have severe growth retardation and multiple birth defects.

Description

Triploidy is a condition caused by having a full extra set of chromosomes. This extra set of chromosomes causes a variety of serious birth defects, placental problems, and severe growth problems in a fetus. In fact, most pregnancies in which the fetus has triploidy end in a spontaneous miscarriage. Very few infants with triploidy survive to term. Of those that do, most are stillborn and those that are born alive usually die shortly after birth. Infants with this lethal condition are generally small due to severe intrauterine growth retardation (IUGR) and they have multiple birth defects, including facial abnormalities, such as cleft lip, heart defects, neural tube defects (spina bifida), and other serious birth defects. The exact pattern of abnormalities depends on whether the extra set of chromosomes was inherited from the mother or from the father. Unfortunately, there is nothing that can be done to treat or cure triploidy.

Genetic profile

Triploidy is a chromosomal disorder. Chromosomes are the structures that contain all of the body's genes (the basic unit of inheritance). Humans have 46 chromosomes in every cell of their body, with the exception of their sperm and egg cells, which contain only 23 chromosomes. When a sperm and an egg unite at conception, the resulting fertilized egg will have 46 chromosomes: half from the mother and half from the father. This fertilized egg will continue to develop and grow into a fetus and, eventually, into a live-born infant with 46 chromosomes in every cell of his or her body.

Of these 46 chromosomes, 22 pairs (or 44 chromosomes) are called autosomes (or nonsex chromosomes) and the twenty-third pair is the sex chromosomes. Women have two X chromosomes (46,XX) and men have an X and Y chromosomes (46,XY). Fetuses with triploidy can be 69,XXX (female), 69,XXY (male), or 69,XYY (male). Twenty-three chromosomes (or one set) are referred to as a haploid set of chromosomes, forty-six chromosomes (or two sets) are referred to as a diploid set of chromosomes, and sixty-nine chromosomes (or three sets) are referred to as a triploid set of chromosomes. A fetus with triploidy has three haploid sets of chromosomes.

Triploidy occurs in several different ways. The extra set of chromosomes can be inherited from the father

(paternal inheritance) or they can be from the mother (maternal inheritance). The most common mechanism for triploidy is the fertilization of a single egg by two sperm. This results in a triploid egg with two sets of paternal chromosomes and one set of maternal chromosomes. This accounts for about 60% of cases of triploidy. The other mechanism is an error in cell division in which an egg cell ends up with 46 chromosomes instead of 23. This egg with 46 chromosomes is fertilized by a sperm with 23 chromosomes, resulting in a fertilized egg with 69 chromosomes, which then has two sets of maternal chromosomes and one set of paternal chromosomes. This mechanism is responsible for about 40% of cases of triploidy. The physical effects of triploidy differ depending on whether the extra set of chromosomes was inherited from the mother (maternally inherited) or from the father (paternally inherited).

In pregnancies in which the extra set of chromosomes is maternally inherited, the fetuses tend to be well formed, with a small head (microcephaly). The placenta in these pregnancies is generally enlarged and cystic (filled with cysts). This type of placenta is often referred to as a hydatiform mole and the pregnancy as a whole may be referred to as a partial molar pregnancy. In pregnancies in which the extra set of chromosomes is paternally inherited, the fetuses have severe growth retardation, a large head, and a small, noncystic placenta.

The physical birth defects seen in triploidy are variable. All fetuses will have some of these birth defects, but very few will have all of them. The birth defects most commonly seen are heart defects, cleft lip, neural tube defects, kidney malformation, abnormal genitalia (males), and defects in the abdominal wall. Regardless of the presence or absence of these birth defects, triploidy is incompatible with life.

Triploidy is a sporadic (or accidental) event. It is not caused by anything that a parent may or may not have done. Unlike some other chromosome abnormalities (trisomy 21 or Down syndrome), triploidy is not associated with a mother's age. This means that there is not an increased risk for triploidy in an older woman's pregnancy. Because triploidy is an accidental event, there is no increased recurrence risk in future pregnancies. A woman who has had one triploid pregnancy is not at any increased risk to have a second one.

Demographics

Triploidy occurs in about 1%–2% of all conceptions, but most of these pregnancies end in early spontaneous miscarriage. Very few pregnancies with a triploid infant go to term. Only 1 in 10,000 infants is born with triploidy, and it is estimated that for every live-born infant

with triploidy, 1,200 have been lost as miscarriages. Most infants with triploidy are either stillborn or die shortly after birth. The longest recorded lifespan of an infant with full triploidy is 10 months, although this length of survival is extremely rare.

There is a milder form of triploidy that is the result of mosaicism, which is the presence of two separate types of cells within the same individual. Infants with mosaic triploidy have both a normal cell line (46,XX or 46,XY) and a triploid cell line (69,XXX or 69,XXY or 69,XYY). These infants can survive to be live born, but they generally have growth retardation, growth asymmetry (their limbs may be different sizes), some of the other birth defects seen in full triploidy, and severe intellectual disability. It is thought that the presence of the normal cell line aids in survival.

Signs and symptoms

Triploidy manifests itself in many different ways. It can be diagnosed both prenatally and at birth.

The diagnosis of triploidy is often made prenatally or during the course of a pregnancy. The diagnosis is often suspected because of an abnormal sonogram or because of an abnormal maternal serum screening test.

A sonogram, or ultrasound, is a common test done during pregnancy that uses sound waves to examine the fetus. There is no known risk to the fetus from an ultrasound. However, a fetus affected with triploidy will often show abnormalities that will warrant further testing to confirm the diagnosis of triploidy. Some of the most common abnormalities seen on a sonogram of a fetus with triploidy include severe growth problems or intrauterine growth retardation (IUGR), an abnormal placenta, and limb abnormalities.

Not every fetus with triploidy will have all of these findings, but most will show some signs that can be detected by sonogram. Abnormal sonogram findings include:

- severe early-onset intrauterine growth retardation (detected as early as 12 to 14 weeks)
- brain abnormalities, including isolated ventriculomegaly (enlarged ventricles), Arnold-Chiari malformation, holoprosencephaly, and agenesis of the corpus callosum
- cleft lip and possible cleft palate
- limb abnormalities, such as clubfoot or syndactyly (webbing of the fingers and toes)
- heart defects
- kidney abnormalities

- abdominal wall defects, such as an omphalocele (an opening in the abdominal wall, which causes the intestines to be located outside the body)
- neural tube defects, such as spina bifida (an opening in the spinal cord)
- oligohydramnios (a decreased amount of amniotic fluid)
- placental abnormalities, including an enlarged placenta or a cystic placenta

In addition to detection by prenatal sonogram, many fetuses with triploidy are detected by an abnormal maternal serum screening test. A maternal serum screening test is a voluntary blood test usually performed in the second trimester of pregnancy. It is not specifically designed to detect triploidy, but often does because of some of the abnormalities seen in triploidy. The blood test measures the amount of certain proteins in the mother's blood. These proteins, alpha-fetoprotein, human chorionic gonadotropin (hCG), and estriol, are all made either by the fetus or by the placenta. These proteins cross the placenta and get into the mother's blood system. By looking at the amount of these proteins present in the mother's blood system, it is possible to screen for certain genetic abnormalities. Because fetuses with triploidy often have abnormal placentas, too much or too little of these proteins are leaked into the mother's system and the blood test results are often abnormal. If a maternal serum screening test is abnormal, the patient should be offered a detailed ultrasound and amniocentesis.

Both prenatal sonograms and maternal serum tests are screening tests. They can pick out individuals with a higher risk to have a fetus with a specific disorder, but they cannot actually give a specific diagnosis. Because of this, if an individual has an abnormal screening test, further diagnostic testing is indicated.

The only way to definitively diagnose triploidy is to have a chromosome analysis (karyotype) done and actually count the number of chromosomes present. In order to do a chromosome analysis during pregnancy, it is necessary to obtain some tissue from the fetus. This is commonly done through either a chorionic villus sampling (CVS) test or through an amniocentesis. During a CVS test, a catheter is used to remove a small piece of tissue from the placenta. Since the placenta and fetus have come from the same fertilized egg, the chromosomes in the placenta are the same as the chromosomes in the fetus. A CVS test is usually done between 10 and 12 weeks of pregnancy. If a patient is further along in the pregnancy when an abnormality is suspected, an amniocentesis may be performed. This test is usually done between 16 and 18 weeks of pregnancy. It involves using a needle to remove some of the amniotic fluid from around the fetus. The amniotic fluid contains fetal skin cells, which

KEY TERMS

Diploid—Two sets of chromosomes; in humans, this is 46 chromosomes.

Haploid—One single set of chromosomes; in humans, this is 23 chromosomes.

Triploid—Three sets of chromosomes; in humans, this is 69 chromosomes.

can then be cultured (grown) and analyzed. The results from these tests can take between one and two weeks. By doing a fetal karyotype (counting the number of chromosomes the fetus has), it is possible to definitely diagnose triploidy. A newer technique, fluorescent in situ hybridization (FISH), is available in some laboratories and results may be available in as little as 24 hours. It is always wise to do a complete karyotype in addition to FISH testing.

Very few fetuses survive to be born to term with triploidy. Those infants that survive do show a very specific pattern of birth defects. Almost all of these infants will have growth retardation and characteristic facial features, including wide-set eyes (hypertelorism), low-set ears, and limb abnormalities, such as clubfoot and syndactyly (webbing of the fingers and toes). Other anomalies include heart defects, kidney malformations, and genital malformations (particularly in males). Once triploidy is suspected in an infant, a blood chromosome analysis (a karyotype) should be performed to confirm the diagnosis. Additionally, the newer technique, FISH, is advised.

Diagnosis

The diagnosis is often suspected in pregnancies due to abnormal growth parameters, abnormalities seen on a sonogram, an abnormal screening test, or an abnormal CVS or amniocentesis result.

The diagnosis in infants is made by physical examination shortly after birth. Severe growth retardation, an abnormal placenta, and physical birth defects first raise the suspicion of triploidy. This diagnosis is then confirmed through a chromosome analysis (karyotype), which is a blood test performed on the infant. A karyotype is a picture of an individual's chromosomes and in this case will show an abnormal number of chromosomes (69 instead of 46).

The diagnosis in infants with the rare mosaic form of triploidy (one normal cell line and one abnormal cell line) may be suspected shortly after birth due to the presence of growth retardation, asymmetrical growth of the limbs,

and other physical birth defects. The diagnosis is then confirmed through a chromosome analysis (karyotype), which, in this case, will show the presence of two cell lines: one normal cell line with 46 chromosomes and an abnormal cell line with 69 chromosomes.

Treatment and management

There is no cure and no treatment for triploidy. Infants that survive to term should receive palliative care, including warmth, nourishment, and comfort, until the parents have a chance to incorporate the diagnosis and make decisions about care options. Surgical correction of birth defects is not indicated given the lethal nature of this diagnosis.

If triploidy is detected during a pregnancy, patients have the option to terminate a pregnancy based upon the lethality of this condition. This is a very personal decision and should be made following complete counseling about the nature and outcome of this diagnosis. If the pregnancy continues, then the mother should be monitored for preeclampsia and hyperthyroidism. There is no need for special interventions, such as fetal monitoring or a caesarean section, based solely on the diagnosis of triploidy given the inevitability of the outcome.

Once the diagnosis has been firmly established, there is no need for heroic measures given the established lethality of the conditions. Infants should be provided with basic supportive care until the family can make decisions.

This diagnosis is devastating for families. The bleak prognosis and lack of treatment can be very shocking. Families should be reassured that there is nothing that they did or did not do that could have prevented the outcome. While grieving is inevitable and appropriate, the family needs time to incorporate the information about the diagnosis. Many families find it helpful to have reminders of their baby, including footprints, photographs, and locks of hair, and the neonatal staff can aid in collecting these materials following the birth of the infant. Parents also need to understand the genetic diagnosis and its implications for future pregnancies. It is important to make sure that they understand the sporadic nature of this diagnosis and that it is unlikely to recur in a future pregnancy.

Prognosis

The prognosis for a fetus or infant with full (non-mosaic) triploidy is very bleak. Many pregnancies end in spontaneous abortion, and those that go to term often result in a stillborn infant or one that dies shortly after birth. The longest recorded survival of an infant with

triploidy is 10 months, although this length of survival is exceedingly rare.

Infants with mosaic triploidy (two cell lines: one normal and one with triploidy) often survive pregnancy but generally have multiple birth defects, severe growth abnormalities, and severe intellectual disability. Their life expectancy is often dependent on the severity of their associated birth defects.

Trismus-pseudocamptodactyly syndrome

Definition

Trismus-pseudocamptodactyly syndrome is a rare genetic condition characterized by the inability to completely open the mouth (trismus), difficulty chewing, short stature, and abnormally short muscle-tendon units in the fingers that cause the fingers to curve or bend when the hand is bent back at the wrist (pseudocamptodactyly).

KEY TERMS

Contracture—A tightening of muscles that prevents normal movement of the associated limb or other body part.

Pseudocamptodactyly—A condition in which the fingers curve or bend when the hand is bent back at the wrist.

Trismus—Inability to open the mouth completely.

Other names for this syndrome are Hecht syndrome and arthrogryposis, distal type 7.

Description

Trismus-pseudocamptodactyly syndrome was first described by pediatrician/geneticist Frederick Hecht and orthopedist Rodney K. Beals of the Oregon Health Sciences University in 1969 as inability-to-open-the-mouth-fully syndrome. Explaining the first descriptive name for the syndrome, individuals affected by trismus-pseudocamptodactyly syndrome cannot fully open the mouth (trismus). In addition, affected individuals are unable to bend their fingers when their wrist is extended (pseudocamptodactyly). The muscles and tendons in the forearms and/or the legs may also be abnormally short, resulting in limited movements and various deformities of the feet, including clubfoot, hammer and claw toes, and tightening of the muscles of the posterior part of the leg, producing other multiple foot abnormalities. The severity of the physical findings in trismus-pseudocamptodactyly syndrome varies from individual to individual.

Trismus-pseudocamptodactyly syndrome is also known as Dutch-Kennedy syndrome, camptodactyly-limited jaw excursion, Hecht syndrome, inability to open mouth completely and short finger-flexor, Hecht-Beals-Wilson syndrome, distal arthrogryposis, and Hecht-Beals syndrome.

Genetic profile

Trismus-pseudocamptodactyly syndrome is a rare condition inherited in an autosomal dominant pattern. In an autosomal dominant condition, only one copy of the mutated, or nonworking, gene for a particular condition is necessary for a person to experience the symptoms associated with the condition. Accordingly, most individuals with an autosomal dominant condition have one working copy and one nonworking copy of the gene for the disorder. Individuals contribute only half of their genetic

information to their children and pass on only one copy of each gene. As a result, there is a 50% chance for a person with trismus-pseudocamptodactyly syndrome to pass on the nonworking gene for that condition and have a child affected with trismus-pseudocamptodactyly syndrome. There is also a 50% chance that a person with trismus-pseudocamptodactyly syndrome will pass on the working gene and have a child unaffected by trismus-pseudocamptodactyly syndrome. Individuals in the same family who inherit the nonworking copy of the gene causing trismus-pseudocamptodactyly syndrome can be affected in different manners and with different symptoms. Symptoms of trismus-pseudocamptodactyly syndrome present in a variety of mild to severe features (variable expressivity). However, in trismus-pseudocamptodactyly syndrome, a high percentage of individuals who inherit the abnormal gene will have some sign of the disorder (high penetrance).

The cause of trismus-pseudocamptodactyly syndrome is related to mutations in the *MYH8* gene (perinatal myosin heavy-chain gene) on the short arm of chromosome 17 (17p13.1).

Demographics

Trismus-pseudocamptodactyly syndrome is a rare condition affecting both men and women equally. It was originally described in a Dutch family and believed to only occur in Dutch families or the descendants of Dutch families in West Virginia. Since the original families were identified, families of other ethnic backgrounds, including Canadians, Taiwanese, and Japanese, have been found to be affected. Accordingly, it is believed that trismus-pseudocamptodactyly syndrome can occur in any race or ethnic background.

Signs and symptoms

Individuals affected by trismus-pseudocamptodactyly syndrome classically present with two main features: limited excursion of the mandible (trismus) and flexion deformity of the fingers that occurs with wrist extension (pseudocamptodactyly). At birth, trismus-pseudocamptodactyly syndrome may be diagnosed based on the infant's clenched fists and inability to fully open its mouth. Additional features include short stature and foot malformations caused by short muscle-tendon units, which prevent normal growth and development. The forms of foot abnormalities caused by short muscle-tendons in the hamstrings, calves, and feet include malformations that occur when the foot is turned inward and downward (equinovarus or talipes equinovarus), inward bending for the front half of the foot (metatarsus varus), and angling foot at the heel with the toes pointing upward and outward (calcaneovalgus

deformity). Different family members who have inherited the same mutated, or nonworking, gene can have symptoms that range from very mild to very severe.

Diagnosis

Diagnosis of trismus-pseudocamptodactyly syndrome is made through a detailed physical exam, medical history, and family history, most often performed by a medical genetics team. Clinical genetic testing is available at this time for *MYH8* mutations.

Treatment and management

The treatment and management of trismus-pseudocamptodactyly syndrome depends on the severity of the symptoms. Most individuals are treated with a combination of physical therapy, speech therapy, occupational therapy, and surgery.

An infant's inability to fully open its mouth can cause severe difficulties with feeding, adequate calorie intake, speech development, and dental care. Speech and physical therapy are recommended to help address jaw issues. Jaw surgery may be necessary to open an infant's jaw for nourishment. The clenched fists found in many infants affected by trismus-pseudocamptodactyly syndrome can cause difficulties in learning to crawl and grasp items. Often infants will learn to crawl on their knuckles. The clenched fists involved with pseudocamptodactyly may also impair manual dexterity and cause occupational disability that requires physical and occupational therapy or surgery. Contractures due to the short muscle-tendons may result in foot abnormalities that, like clenched fists, may delay milestones. Affected infants may require surgical correction of contractures and foot abnormalities in order to walk.

Adults affected by trismus-pseudocamptodactyly syndrome continue to have issues with inability to open their mouths fully, short muscle-tendons, and foot anomalies. Although many individuals pursue surgical options, there is no consensus on the optimal treatment. In one report, endoscopic surgery to release the jaw in one patient resulted in recurrence three months postoperatively. Another technique that had some success was a passive stretching of the mouth with tongue blades. Early treatment of trismus can prevent or minimize many of the conditions. Passive motion, applied several times per day, has been shown to be more effective than static stretching for keeping short muscle-tendons supple. Recent research has shown that passive motion provides significant reduction in inflammation and pain. Ongoing physical therapy and stretching of contractures caused by short muscle-tendons may help maintain optimal muscle length over

QUESTIONS TO ASK YOUR DOCTOR

- Which medical specialists does my child need to see to help with feeding difficulties?
- When will surgery be considered for my child?
- What type of therapy will my child need?
- What are the chances of having another child affected with trismus-pseudocamptodactyly syndrome?

time, allowing improved range of motion and preventing relapse after surgery.

General anesthesia and muscle relaxants do not relieve the trismus or increase the jaw's opening. Since an open mouth is necessary to intubate in the traditional manner, general anesthesia for any surgery can be difficult and hazardous. Several reports on intubation techniques are found in the anesthesia literature that recommend techniques such as avoiding muscle relaxants and using fiberoptic-assisted nasotracheal intubation, blind nasotracheal intubation, or mask anesthesia with spontaneous ventilation to assess the delivery of anesthesia and surgery. During all surgical procedures, it is recommended that a surgeon experienced in obtaining an emergency surgical airway be available.

Prognosis

Most individuals with trismus-pseudocamptodactyly syndrome can achieve a mouth opening large enough for food and speech, and a sufficient range of motion in their affected joints to live healthy, complete lives. In many individuals, physical therapy and stretching of contractures caused by short muscle-tendons may help maintain optimal muscle length, allowing improved range of motion and quality of life. However, the severe contractures and pseudocamptodactyly that appear in some individuals affected by trismus-pseudocamptodactyly syndrome may impair manual dexterity and cause occupational disability that places physical restrictions.

Trisomy see **Chromosomal abnormalities**

Trisomy 8 mosaicism syndrome

Definition

Trisomy 8 is defined as the presence of three full copies of chromosome 8 in all of a person's cells. Mosaic trisomy 8 describes the situation that occurs when only a portion of these cells contains three copies of chromosome 8, while others contain the usual two copies of that chromosome. For example, people with mosaic trisomy 8 may have cells in their blood and other tissues with the normal chromosome number, but they may have cells in their skin with trisomy 8.

Description

The condition is sometimes also referred to as trisomy 8 mosaicism syndrome (T8mS) and mosaic Warkany

syndrome. Common characteristics of T8mS are distinct facial features, including low-set or abnormally shaped ears and a bulbous-tipped nose; eye abnormalities like strabismus and corneal clouding; bone and tissue abnormalities; various structural heart problems; palate abnormalities; hydronephrosis; cryptorchidism; mild to moderate mental delays; and deep hand and feet creases. These characteristics tend to vary widely from person to person.

Genetic profile

The presence of three copies of a chromosome typically arises from a process called nondisjunction. This happens during the very complex process of cell division. It can occur during meiosis, the process of cell division within the sperm and eggs prior to fertilization. It can also happen during mitosis, the process of cell division in the zygote after fertilization.

A fertilized human zygote usually has 46 chromosomes in total. In mitosis, the zygote's cells divide and duplicate themselves evenly, keeping the chromosome number the same in all of the duplicated cells. If nondisjunction occurs, a pair of chromosomes does not divide evenly. This can result in too few chromosomes in some cells, which is called monosomy. It also results in too many chromosomes in other cells. If nondisjunction involves chromosome 8, it can lead to trisomy 8.

When nondisjunction happens during mitosis and causes trisomy 8, it only causes trisomy 8 in a portion of that individual's cells. A single cell then has trisomy 8, and these cells continue to duplicate themselves in certain organs and tissues. At the same time, cells with the normal number of chromosomes duplicate themselves in other organs and tissues. In the end, the affected person has a combination of cells with the normal chromosome number and those with trisomy 8, which is T8mS. This may occur in varying different tissues of that person, and the exact ones cannot be predicted. Depending on when the nondisjunction happened, the person may have few or many cells with trisomy 8.

Nondisjunction is a cell division error that occurs by chance. Thus, no parent has control over this process and cannot influence the number of chromosomes his or her child receives at, or after, conception. In turn, T8mS is considered an unpredictable event that typically carries a very low recurrence risk for that person's parents and family. Unlike other conditions involving nondisjunction, like Down syndrome, T8mS has not been strongly associated with a mother's or father's age at conception.

Most people with T8mS do not have a family history of the condition, since it usually occurs by chance.

Demographics

Full trisomy 8 occurs in about 0.7% of spontaneous miscarriages. It is estimated to occur in about 0.1% of recognized pregnancies. When seen at birth, it is almost always due to mosaic trisomy 8 as opposed to full trisomy 8. A 2009 resource reported that the annual incidence of T8mS varies between 1 in 25,000 and 1 in 50,000.

T8mS has been reported worldwide, being slightly more common in males than in females.

Signs and symptoms

Characteristics of T8mS vary. In other chromosome mosaicism conditions, more severe symptoms and a worse prognosis are associated with a larger proportion of cells with an abnormal chromosome number being present. Interestingly, that does not seem to be the case in T8mS. The percentage of cells with trisomy 8 does not appear to correlate with the types of symptoms the affected person experiences.

The creases on the palms and soles of people with T8mS are the most unique characteristic of the condition. On the palms there may be more arches than usual on the fingertips and a single crease running across the palm. The creases are often deep and vertical, with a furrowed appearance, on the soles of the feet.

People with T8mS often have distinct facial characteristics. This can include a wide upturned nose, thicker and downturned lower lip, and low-set and prominent ears that may not be shaped in the usual way. They may also have abnormalities of the palate, including a cleft (opening) or highly arched palate.

Intellectual disability can occur with the condition, and the degree of mental delays varies from mild to moderate.

Other findings in T8mS can include those of the bone and tissues. These may be narrow shoulders, absent knee caps, abnormally shaped toes, tighter joints, slender palms, extra or missing ribs, and curving of the spine.

Eye abnormalities are seen in T8mS, and the two most common findings are corneal clouding and strabismus (a turning-in of the eye). These may or may not cause significant vision problems and require treatment. Rarer eye problems can include a smaller eye size, smaller eye openings, droopy eyelids, wide-set eyes, tilted optic discs, nearsightedness, retinal abnormalities, and epicanthic folds.

Occasional other characteristics can include structural heart problems, hydronephrosis, underdeveloped genitalia, cancer, and testes that have not descended into the scrotal sacs.

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Chorionic villus sampling (CVS)—A procedure involving removal of a small placenta sample during pregnancy to obtain fetal chromosome results.

Chromosome—A microscopic thread-like structure found within each cell of the body and consisting of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Cryptorchidism—Failure of descent of the testis from the abdominal cavity into the scrotum.

Epicanthic fold—Fold of skin of the upper eyelid continued over the inner edge of the eye.

Hydronephrosis—Obstruction of the tube that carries urine from the kidney into the bladder causing the pelvis and kidney duct to become swollen with excess urine.

Optic disc—The circular area at the back of the eyeball where the optic nerve connects to the retina.

Strabismus—Condition in which the eyes are not properly aligned with each other.

Zygote—The sperm and egg combined to form the initial cell when a new organism is produced by means of sexual reproduction.

Diagnosis

Suspicion about T8mS are usually based on a child being born with unique characteristics, since there is typically no reason one would suspect the condition. Blood chromosome testing is widely available to diagnose chromosome abnormalities. If enough cells are carefully analyzed in the laboratory, T8mS can often be found in a blood sample.

In situations in which a child with multiple characteristics has normal blood chromosome results, other tissues like the skin can be studied for their chromosome makeup. A trained physician can do a brief procedure

QUESTIONS TO ASK YOUR DOCTOR

- What is the cause of trisomy 8 mosaicism syndrome?
- What kind of medical specialists should evaluate my child?
- Are there any treatments for trisomy 8 mosaicism syndrome?
- How can I find another family who also has a child affected with trisomy 8 mosaicism syndrome?
- What is the chance of having another child affected with trisomy 8 mosaicism syndrome?

called a skin biopsy to obtain a small skin sample. During this, the physician takes a pencil eraser-sized piece of skin from a child's arm or back. Sometimes this testing reveals the presence of trisomy 8 in skin cells, which would confirm a diagnosis of T8mS.

Many characteristics of T8mS will not be seen during a pregnancy. However, a woman may be offered a routine prenatal chromosome test for other reasons, such as her age or family history. A chorionic villus sampling (CVS) or amniocentesis procedure, done in the first two trimesters of pregnancy, can usually identify trisomy 8. Depending on the number of cells that are carefully studied, T8mS may also be identified.

In about 1%–2% of CVS procedures that are performed, chromosomal mosaicism is found. However, this is confined to the placenta and does not represent the chromosomal status of the fetus. Additionally, as reported in the literature, a few babies born with T8mS had mothers who had completely normal amniocentesis chromosome results during their pregnancies. For an unknown reason, amniocentesis may not provide the most accurate results with respect to T8mS. This makes it difficult when counseling and providing information to couples during pregnancy with respect to T8mS.

Individuals with T8mS can also be formally assessed by a medical geneticist and genetic counselor to aid in diagnosis, discussion of testing options, and interpretation of test results.

Treatment and management

There is no cure for T8mS. Therefore, treatments are based on a person's signs and symptoms.

A cleft palate can be repaired through stages with surgery, often first occurring in the first year of life. This usually requires a multidisciplinary team consisting of a plastic surgeon, pediatric dentist, pediatric anesthesiologist, nurses, dietician/feeding specialist, and social worker.

Hydronephrosis, if severe enough, can warrant surgery shortly after birth. The goal is to open the blocked area of the urinary tract and clear the obstruction into the kidney. Surgery may involve a team approach, including a pediatric urologist, pediatric nephrologist, nurses, and surgery technicians.

Congenital heart defects, if severe enough, can require surgery. Surgery varies depending on the problem and may involve a team, including a pediatric cardiologist, pediatric cardiovascular surgeon, pediatric anesthesiologist, pediatric cardiovascular radiologist, nurses, and surgery technicians.

Strabismus can often be treated with patching therapy or surgery. This may require a team involving a pediatric ophthalmologist, pediatric anesthesiologist, orthoptist, nurses, and surgery technicians. Severe corneal clouding may lead to vision problems and can sometimes be treated with surgery, laser therapy, or corneal transplants.

Undescended testicles or testes can be brought down to the proper location in the scrotal sacs by a brief surgical procedure. This can involve a team, including a pediatric urologist, pediatric anesthesiologists, and nurses.

Some characteristics of T8mS do not necessitate treatment, as they cause no medical harm. Examples of these include facial features, hand/foot creases, and some tissue and bone changes.

Mental delays and intellectual disability may be assessed by a child development team or early childhood program. Extra assistance is sometimes available through early intervention programs and special education in schools. Social workers are useful to connect families to helpful resources.

Prognosis

People with T8mS have a prognosis that is entirely dependent upon the symptoms they experience. Someone born with a severe congenital heart defect may have a poorer prognosis for survival, growth, and development based on this. The average lifespan for someone with T8mS is estimated to be near normal in the literature. Medical treatments and surgeries continue to offer hope.

Trisomy 13

Definition

Trisomy 13, also called Patau syndrome, is a congenital (present at birth) disorder associated with the presence of an extra copy of chromosome 13. The extra chromosome 13 causes numerous physical and mental abnormalities, especially heart defects. Dr. Klaus Patau reported the syndrome and its association with trisomy in 1960.

Description

Children normally inherit 23 chromosomes from each parent, for a total of 46 chromosomes. A typical human being has 46 chromosomes: 22 pairs of non-sex-linked chromosomes and one pair of sex-linked

Deformed fingers and darkened skin of a patient with trisomy 13 or Patau syndrome. (Biophoto Associates/Science Source)

chromosomes that determine the child's sex. Sometimes a child may end up with more than 46 chromosomes because of problems with the father's sperm or the mother's egg, or because of mutations that occurred after the sperm and the egg fused to form the embryo (conception).

Normally, there are two copies of each of the 23 chromosomes: one from each parent. A condition called trisomy occurs when three, instead of two, copies of a chromosome are present in a developing human embryo. An extra copy of a particular chromosome can come either from the egg or sperm, or because of mutations that occur after conception.

The most well-known trisomy-related disorder is Down syndrome (trisomy 21), in which the developing embryo has an extra copy of chromosome 21. In trisomy 13, the developing embryo has three copies of chromosome 13.

An extra copy of chromosome 13 is not the only cause of trisomy 13. Other changes in the chromosome, such as mispositioning (translocation), can also result in the characteristics associated with the disorder. In these cases, an error occurs that causes a portion of chromosome 13 to be exchanged for a portion of another chromosome. There is no production of extra chromosomes, but a portion of each affected chromosome is "misplaced" (translocated) to another chromosome.

Trisomy 13 causes serious physical and mental abnormalities including heart defects; incomplete brain development; unusual facial features such as a sloping forehead, a smaller than average head (microcephaly), small or missing eyes, low-set ears, and cleft palate or hare lip; extra fingers and toes (polydactyly); abnormal genitalia; spinal abnormalities; seizures; gastrointestinal hernias, particularly at the navel (omphalocele); and

mental retardation. Due to the severity of these conditions, fewer than 20% of those affected survive beyond infancy.

Genetic profile

When an extra copy (trisomy) of a chromosome is made, it may either be a total trisomy (in which an extra copy of the entire chromosome is made), or partial trisomy (in which only one part of the chromosome is made an extra time).

In most cases of trisomy, errors in chromosome duplication occur at conception because of problems with the egg or the sperm that are coming together to produce an offspring. In these cases, every cell in the body of the offspring has an extra copy of the affected chromosome. However, errors in chromosome duplication may also occur during the rapid cell division that takes place immediately after conception. In these cases, only some cells of the body have the extra chromosome error. The condition in which only some of the cells in the body have the extra chromosome is called mosaicism.

Seventy-five to eighty percent of the cases of trisomy 13 are caused by a trisomy of chromosome 13. Some of these cases are the result of a total trisomy, while others are the result of a partial trisomy. Partial trisomy generally causes less severe physical symptoms than full trisomy. Ten percent of these cases are of the mosaic type, in which only some of the body's cells have the extra chromosome. The physical symptoms of the mosaic form of trisomy 13 depend on the number and type of cells that carry the trisomy.

Most cases of trisomy are not passed on from one generation to the next. Usually they result from a malfunction in the cell division (mitosis) that occurs after conception. At least 75% of the cases of trisomy 13 are caused by errors in chromosome replication that occur after conception. The remaining 25% are caused by the inheritance of translocations of chromosome 13 with other chromosomes within the parental chromosomes. In these cases, a portion of another chromosome switches places with a portion of chromosome 13. This leads to errors in the genes on both chromosome 13 and the chromosome from which the translocated portion originated.

Demographics

Trisomy 13 occurs in approximately 1 in 10,000 live births. In many cases, miscarriage occurs, and the fetus does not survive to term. In other cases, the affected individual is stillborn. As appears to be the case in all trisomies, the risk of trisomy 13 seems to increase with the mother's age, particularly if she is over 30 when

pregnant. Male and female children are equally affected, and the syndrome occurs in all races.

Signs and symptoms

The severity and symptoms of trisomy 13 vary with the type of chromosomal anomaly, from extremely serious conditions to nearly normal appearance and functioning. Full trisomy 13, which is present in the majority of the cases, results in the most severe and numerous internal and external abnormalities. Commonly, the forebrain fails to divide into lobes or hemispheres (holoprosencephaly) and the entire head is unusually small (microcephaly). The spinal cord may protrude through an opening in the vertebrae of the spinal column (myelomeningocele). Children who survive infancy have profound mental retardation and may experience seizures.

Incomplete development of the optic (sight) and olfactory (smell) nerves often accompany the brain abnormalities described above. The eyes may be unusually small (microphthalmia) or one eye may be absent (anophthalmia). The eyes are sometimes set close together (hypotelorism) or even fused into a single structure. Incomplete development of any structures in the eye (coloboma) or failure of the retina to develop properly (retinal dysplasia) will also produce vision problems. Individuals with trisomy 13 may be born either partially or totally deaf, and many are subject to recurring ear infections.

The facial features of many individuals with trisomy 13 appear flattened. The ears are generally malformed and low-set. Frequently, children with the disorder have a cleft lip, a cleft palate, or both. Other physical characteristics include loose folds of skin at the back of the neck, extra fingers or toes (polydactyly), permanently flexed (closed) fingers (camptodactyly), noticeably prominent heels, "rocker-bottom foot," and missing ribs. Genital malformations are common and include undescended testicles (cryptorchidism), an abnormally developed scrotum, and ambiguous genitalia in males, or an abnormally formed uterus (bicornuate uterus) in females.

In nearly all cases, affected infants have respiratory difficulties and heart defects, including atrial and ventricular septal defects (holes between chambers of the heart); malformed ducts that cause abnormal direction of blood flow (patent ductus arteriosus); holes in the valves of the lungs and the heart (pulmonary and aortic valves); and misplacement of the heart in the right, rather than the left side of the chest (dextrocardia). The kidneys and gastrointestinal system may also be affected with cysts similar to those seen in polycystic kidney disease. These abnormalities are frequently severe and life threatening.

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10–12 weeks of gestation. Under ultrasound guidance a needle is inserted either through the mother's vagina or abdominal wall and a sample of cells is collected from around the fetus. These cells are then tested for chromosome abnormalities or other genetic diseases.

Chromosome—A microscopic thread-like structure found within each cell of the body consisting of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Karyotyping—A laboratory procedure in which chromosomes are separated from cells, stained, and arranged so that their structure can be studied under a microscope.

Mosaicism—A genetic condition resulting from a mutation, crossing-over, or nondisjunction of chromosomes during cell division, causing a variation in the number of chromosomes in the cells.

Translocation—The transfer of one part of a chromosome to another chromosome during cell division. A balanced translocation occurs when pieces from two different chromosomes exchange places without loss or gain of any chromosome material. An unbalanced translocation involves the unequal loss or gain of genetic information between two chromosomes.

Trisomy—The condition of having three identical chromosomes, instead of the normal two, in a cell.

Ultrasound—An imaging technique that uses sound waves to help visualize internal structures in the body.

Partial trisomy of the distal segment of chromosome 13 generally results in less severe, but still serious, symptoms and a distinctive facial appearance including a short upturned nose, a longer than usual area between the nose and upper lip (philtrum), bushy eyebrows, and tumors

made up of blood capillaries on the forehead (frontal capillary hemangiomas). Partial trisomy of the proximal segment of chromosome 13 is much less likely to be fatal and has been associated with a variety of facial features including a large nose, a short upper lip, and a receding jaw. Both forms of partial trisomy also result in severe mental retardation.

Beyond one month of age, other symptoms include: feeding difficulties and constipation, reflux disease, slow growth rates, curvature of the spine (scoliosis), irritability, sensitivity to sunlight, low muscle tone, high blood pressure, sinus infections, urinary tract infections, and ear and eye infections.

Diagnosis

Trisomy 13 is detectable during pregnancy through the use of ultrasound imaging, amniocentesis, and chorionic villus sampling (CVS). At birth, the newborn's numerous malformations indicate a possible chromosomal abnormality. Trisomy 13 is confirmed by examining the infant's chromosomal pattern through karyotyping or another procedure. Karyotyping involves the separation and isolation of the chromosomes present in cells taken from an individual. These cells are generally extracted from cells found in a blood sample. The 22 non-sex-linked chromosomes are identified by size, from largest to smallest, as chromosomes 1 through 22. The sex-determining chromosomes are also identified. Trisomy 13 is confirmed by the presence of three, rather than the normal two, copies of chromosome 13.

Treatment and management

Some infants born with trisomy 13 have severe and incurable birth defects. However, children with better prognoses require medical treatment to correct structural abnormalities and associated complications. For feeding problems, special formulas, positions, and techniques may be used. Tube feeding or the placement of a gastric tube (gastrostomy) may be required. Structural abnormalities such as cleft lip and cleft palate can be corrected through surgery. Special diets, hearing aids, and vision aids can be used to mitigate symptoms. Physical therapy, speech therapy, and other types of developmental therapy will help the child reach his or her potential.

Since the translocation form of trisomy 13 is genetically transmitted, genetic counseling for the parents should be part of the management of the disease.

Prognosis

Approximately 45% of infants with trisomy 13 die within their first month of life; up to 70% in the first six months; and more than 70% by one year of age. Survival

to adulthood is very rare. Only one adult is known to have survived to age 33.

Most survivors have profound mental and physical disabilities; however, the capacity for learning in affected children varies from patient to patient. Older children may be able to walk with or without a walker. They may also be able to understand words and phrases, follow simple commands, use a few words or signs, and recognize and interact with others.

Paul A Johnson

Tuberous sclerosis complex

Definition

Tuberous sclerosis complex (TSC) is a genetic condition that affects many organ systems, including the brain, skin, heart, kidneys, eyes, and lungs. Benign (noncancerous) growths or tumors called hamartomas form in various parts of the body, disrupting their normal functions.

Description

The term "tuberous sclerosis" refers to the small, knoblike growths in the brain of patients with TSC that were found upon autopsy and, today, can be viewed using computed tomography (also called a CT scan). The condition is also referred to as tuberoses sclerosis or simply tuberous sclerosis. The designation tuberous sclerosis complex is used to distinguish this condition from another genetic condition called Tourette syndrome that is abbreviated TS.

Persons with TSC have a variety of symptoms ranging from very mild to severe. Affected individuals may experience no serious health problems and, in the absence of a thorough clinical examination, may go through life without knowing that they are affected. Conversely, patients with TSC may have problems with behavioral, mental, and emotional functions as well as with their kidneys, heart, and eyes. In addition, specific skin abnormalities, often medically insignificant, are among the most common symptoms of TSC.

Genetic profile

TSC is an autosomal dominant genetic disorder caused by a single change or alteration in a gene called a mutation in either the *TSC1* gene, located on chromosome 9, or the *TSC2* gene, located on chromosome 16. Approximately two-thirds (66%) of patients with TSC have it as the result of a new change in one of the TSC genes; that is, it was not inherited from one of their parents. When a new change occurs, it most commonly occurs in the *TSC2* gene. An individual must have a mutation in one of these two copies of a TSC-causing

A retinal photograph of an astrocytoma in the retina of a patient affected by tuberous sclerosis. (Paul Whitten/Science Source)

gene in order to develop the condition. In addition, a person who has been diagnosed with TSC and who, therefore, has a genetic mutation in one of the TSC genes has a 50% chance of passing on the genetic mutation to his or her offspring. Laboratory testing for changes in the TSC genes is not currently available.

TSC is a condition that can be caused by a change in either one of two separate genes. In addition, people who have the same change in the same gene may have very different medical problems and symptoms.

TSC1 is responsible for producing the protein hamartin and *TSC2*, tuberin. Both genes are known as tumor suppressor genes, meaning that their normal function is to prevent the growth of tumors. Conversely, when gene function is altered, tumor growth results. Research on how the disruption of either protein results in the clinical condition of TSC is ongoing.

It is currently believed that every person who inherits or develops a mutation in either the *TSC1* or *TSC2* gene will develop some form of TSC. However, the severity of the disease, with its wide range of symptoms and complications, cannot accurately be predicted by identifying the specific gene mutation.

Germline mosaicism can explain the rare occurrence of unaffected parents having more than one child with TSC. Germline refers to the gonadal cells (sperm in males and eggs in females) and mosaicism refers to the presence of different cell lines in any given individual. A person with germline mosaicism for either the *TSC1* or *TSC2* gene is not affected with TSC but may have an affected child. Unaffected parents of a child with TSC are quoted a 2%–3% chance of having additional affected children. Typical genetic testing methods are performed on somatic (nongermline) tissues such as blood or skin and, therefore, will not detect germline mosaicism.

Demographics

Although tuberous sclerosis complex is considered to be a rare condition, estimates of the prevalence of the disorder have increased as clinical testing methods have improved. In the United States, as many as 1 child in 6,000 born is affected with TSC and about 50,000 people are currently living in the United States with the disease. TSC is seen in all ethnic groups and populations and, worldwide, there are between one and two million cases.

Signs and symptoms

The basic underlying cause for illness and, less often, death due to tuberous sclerosis complex is the development of growths called hamartomas throughout the body. Hamartoma is a general term used to describe tumor-like

growths that are not cancerous and are composed of cells usually found in that site but poorly developed. While these growths are typically benign (i.e., not cancerous), their presence often disrupts the normal functions of a particular organ system. The various hamartomas found in TSC patients can be further distinguished and classified by their location and their histological properties—that is, their physical composition and characteristic appearance under a microscope. As each hamartoma is comprised of different cellular elements, each one has a particular name. For example, while both are hamartomas, a fibroma is comprised of connective tissue whereas a lipoma is made up of fat cells.
